It should seem from this, and from various other collateral circumstances, that the grey mullet is the *Ramado* of Nice, the *M. capito* of Cuvier; and Cuvier himself seems to have been perfectly aware of the confusion which had been introduced into the history of this fish. He says distinctly, in a note to the last edition of the *Règne Animal*, that “Linnæus, and many of his successors, have confounded all the European mullets under one single species (their *Mugil cephalus*).”

This is perhaps not to be wondered at. Linnæus found a description of mullets in the Mediterranean, and he observed in the North Seas one not essentially different, and thus he fell into the mistake. There is no question, however, that the common mullet, which is not a rare fish on many parts of our coasts, is *capito*, not *cephalus*. They are remarkably lively fishes, particularly fond of fresh water, and very dexterous in managing themselves. On the south and south-east of England they are very common; and they occur both on the south and the north of Ireland, and on some parts of the Scottish coasts, though there they are not so general or so numerous. These fishes are in fact a sort of scavengers of the water, and come near the shores, equally partial to the scum and the dregs. Greasy substances, and also animal matters in a semi-putrid state, are not rejected by them; and they may be seen at one time skimming the surface for what floats, and at another time poking with their noses in the mud for whatever is to be found there suitable to their very peculiar sort of

palate. They are also particularly fond of flies, which appears to be one of their inducements for ascending so far up the estuaries of the rivers, though it does not appear that they get above the tide-way, or even remain till a second tide overtake them at the top of their excursion. They are very familiar, and can be kept in ponds, where they soon become so domesticated that they assemble at their accustomed hour in order to be fed. In their natural rambles they are liable to be entangled by shallows, and among reeds and other obstacles. They have great powers of leaping, and when enclosed, even in a net, it is difficult to prevent them from springing over the head line, and making their escape. Indeed, the over-leaping of obstacles appears to be instinctive with them; and, as compared with many fishes, a grey-mullet pond would require lofty banks, in the same manner as a deer-park requires lofty walls. This fish rises freely to artificial flies; and during the flood tide, in those rivers which they visit abundantly, they afford excellent sport. Bait-fishing is not so successful with the grey mullet, because its mouth is not accustomed to receive any substance so large as a baited hook. Contrary to the opinion sometimes stated, that mullets never seize living food, it may, however, be urged that they rise to the fly. It is usually said that the river Arun, which enters the English Channel at Arundel, furnishes the best grey mullets of any in England, and that they ascend the river as far as twenty miles, and thus afford excellent angling, especially toward the upper part of their range. The size of fishes is not a very definite matter, but that of the common grey mullet may be estimated at about a foot and a half. Mullet spawn in the warm weather about Midsummer, and in the course of about six weeks, or two months, the young are about an inch in length. They then keep much in the salt water, but alternate between it and the fresh. Indeed it appears, from experiments which have actually been made, that if mullets, in this early stage, are placed in fresh-water ponds of sufficient size, they succeed as well in gathering flesh and fat as if left to their natural habits, and their usual alternation of salt and fresh water.

The short Grey Mullet (M. curtus). For the knowledge of this species we are indebted to Mr. Yarrell. Its body is much shorter and deeper than that of the former species, and its head wider, and also more pointed. The only species which Mr. Yarrell met with was about two inches in length.

Thick-lipped Grey Mullet (M. chelo). This species has been long known as a native of the Mediterranean, but it has only recently been added to the list of British fishes. The characters are:—The head of moderate size; the upper lip thick, the lower one less so; and the maxillary bone curved. This species of grey mullet comes to the estuaries of rivers, in the south of England at least, during the winter months, and the best account of them is by Mr. Couch, whose observations on the fishes of the Channel, as published in Mr. Yarrell's work, are highly valuable.

“This grey mullet,” says Mr. Couch, “is gregarious, frequenting harbours and the mouths of rivers in the winter months in large numbers, all of which are just of one size; but the fish which I shall here describe was taken, with about four hundred others, as they were left in a pool of our river, forsaken by the tide. This species has, like the other, the habit of escaping from a net by leaping over the head lines.

The length of the specimen was ten inches ; the head wide, depressed ; the eyes one inch apart, and three-eighths of an inch from the angle of the mouth, not connected with any membrane ; nostrils close together, and, while the fish is alive, moveable on each contraction of the mouth ; a prominent superior maxillary bone, minutely notched at its lower posterior edge ; upper lip protuberant and fleshy, with a thin margin minutely notched or ciliated ; the lip appears behind as projecting under the maxillary ; carina of the under jaw prominent and square ; edge of the lower lip fine and simple ; body solid, round over the back ; pectoral fins high on the side, pointed, round below, the first rays short ; the first dorsal fin five inches and three-eighths from the snout ; the organ of the first three rays approximate, the first ray the longest ; the first two rays of the anal fin short ; tail broad, concave ; scales large ; colour of the head and back greenish ; all besides silvery, with six or seven parallel lines along the sides of the same colour as the back."

There are two or three other species of mullet in the Mediterranean, of which the golden mullet and the jumping mullet are mentioned by Risso. The first of these partakes of the characters both of *Capito* and *Cephalus*, and the second more resembles the former of these. There is still another small species in the Mediterranean (*M. labeo*), with the lips very thick in proportion, and crenulated at their margins. The Indian seas, and the seas of some parts of America and of New Holland, also have their mullets, but it does not appear that any of them are of very predominating importance. Of the seas of Europe, the Mediterranean is by far the most abundant in this genus of fishes, and vast numbers of them are taken about the Balearic Islands and on the east coast of Spain. As is the case with most fishes that throng toward the shores at particular seasons of the year, those mullets are taken in much greater abundance than can be used in a recent state at the time, and therefore they are stored up, after being salted—thus affording a seasonable supply to people whose religion enjoins them to feed on fish very frequently.

MUGWORT is the *Artemisia vulgaris* of Linnæus, a common British weed found everywhere.

MULBERRY. See MORUS.

MULLEIN is the *Verbascum thapsus* of Linnæus, a well-known British plant, usually called "shepherd's club."

MULLUS—RED MULLET, or, in some of the species, SURMULLET. A very celebrated genus of spinous-finned fishes, belonging to the perch family. Two species have been well known as inhabiting the Mediterranean ever since the time when the Romans began to carry their luxury in the eating of fish to that remarkable pitch to which it was brought among them. The characters of the genus may be briefly stated as follow : the body thick and oblong ; the profile of the forehead from the eyes sloping so rapidly as to be nearly perpendicular. The body covered with large scales, which very readily come off, and are understood to be shed annually. Two distinct dorsal fins on the back ; the first with spinous rays, about seven in number, and with a short free spine immediately in advance, and the second with flexible rays. There are teeth in the lower jaw and the palate only ; two well-produced cirri or beards at the symphysis of the lower jaw, and the gill-flap with

four rays. All the mullets are remarkable for the beauty of their colours, which are red and yellow of greater brilliancy than are to be found in most fishes.

It is probable that the striped red mullet was the most celebrated one in the time of the Romans ; though perhaps in those days the distinction between it and the plain one was not attended to. The grand object of the Roman epicure was to get a red mullet, and the larger the better, which shows that the eye was more attended to than the palate in the matter of those very costly fishes. This held true also in those cases of the *Coryphæne* (we believe), which, passing through the prismatic colours in the agonies of death, was first displayed to the guests expiring, and then cooked in their presence, in order that they might make sure that the fish seen and the fish tasted were one and the same. The mullet also passes through various colours in dying ; and it is a very beautifully coloured fish, whether dead or alive. The common account is, that the name *mullus* is derived from the red slippers or sandals worn by the Roman consuls during the republic, and continued by the emperors afterwards. Those sandals were marks of distinction, not worn by any but those dignitaries ; and thus the name of these fishes after them shows that mullets were not fare for every man, or indeed any man's every-day fare. The striped red mullet, or surmullet, is by much the more plentiful of the two which are found in the Mediterranean ; it also grows to a much larger size than any of the others, which indeed is rarely, if ever, found so heavy as the most esteemed weights mentioned by the Romans. When luxury was at its height, a mullet of three pounds' weight brought an ample reward to the fisherman who caught it ; and if it reached four pounds and a half, it was quite a fortune—fifty, sixty, and even eighty pounds a piece were given for mullets to set out a Roman feast ; but it may be possible that those costly ones may have been the plain red mullet, which, though a smaller fish than the other, is more richly coloured ; for there is so much confounding of one species with another in the Roman accounts that one can come to no absolute decision. We believe the fact to be that the surmullet, or striped red mullet, is a very palatable fish when in proper condition, and that the plain red mullet is still better.

On the southern shores of Britain, where the striped mullet, though not one of the most abundant of fish, certainly is not rare, the size is seldom more than a foot long, and in no instance above fourteen inches. Three pounds and a half is about the weight of one of the largest in the best condition, which falls far short of the Roman fish. This mullet is found in the London market, at almost all seasons of the year ; and therefore it cannot be looked upon as a migratory fish. The following passage from Mr. Yarrell throws so much light upon the management of this fish, as a market commodity, that we shall quote it at length : "The striped red mullet has been considered migratory, but it appears in the shops of the London fish-mongers throughout the year, though in much greater plenty during May and June, at which time their colours are more vivid, and the fish, as food, in the best condition. If closely examined, it will be observed that, where the scales happen not to have been removed, the natural colour is little more than a pale pink, passing into white on the belly, the lower part of the sides having two or three longitudinal stripes ; but that the mixture of purple and bright red, which

ornaments various parts of the fish, is the consequence of violence; every scale removed by force (and but little is necessary) increases this colour; it is produced by extravasated blood lying under the transparent cuticle, but above the true skin."

The spring is the spawning time with these mullets, and when they come into their best condition, in summer, it is immediately after recovering their flesh subsequent to the labours of that operation. The young surmulletts grow pretty fast, so that by the end of October in the first year they have acquired about half the length and one-eighth of the weight of the average ones found on our coast. Mullet appear to be chiefly ground feeders; and the beards, as they are called, are no doubt intimately connected with the finding of their food, as they are in other ground fishes that possess them. The usual supposition is, that those appendages are very delicate organs of touch, though how they act it is not easy to say. The fish that possess them have very frequently the eyes directed upwards, in a different direction altogether from the mouth; but whether the beards of the mullet act simply as feelers under the fish, or assist in raising it up (for they are very muscular), it is not easy to say. It is certain, however, that mullet do feed chiefly at the bottom of the water; for though a good many are taken in the surface nets, it is probable that this takes place chiefly when they are shifting their ground from one locality to another; for the greatest number, and those in the best condition, are got by trawl nets, worked at the bottom. What the food may be is not very well known; but, from the smallness of the teeth, it cannot be of a very obstinate nature.

The striped mullet is liable to some differences of colour, being of a brighter red not only at different seasons, but in different individuals at the same season; and altogether this is one of the most interesting of our fishes.

PLAIN RED MULLET (*M. barbatus*). *Barbatus*, or bearded, is by no means happily applied to this species, because the striped one is as completely bearded as the present species. This one does not attain so large a size as the former; but its colour is finer, at least in those specimens which are in high condition. The back and sides are a very delicate pure red, of very nearly what is called the fundamental colour, and this passes very gradually and softly into silvery white on the under part. The frontal line in this one is still more perpendicular than in the striped species. The scales are smaller, the first dorsal fin is more elevated, and the second one differently shaped; so that, independently of the colours, the specific difference is well made out.

It is probable, however, that either this last species is subject to some varieties of colouring, or that there are variations in the colours of the former one; for Mr. Couch mentions that in two specimens which he obtained in the Channel, answering of course in form to the plain red mullet, the sides and part of the belly were dark red, and there was a longitudinal stripe of yellow below the lateral line, while the back, in both specimens we believe, was of a paler red than it is even in the striped mullet. But the typical red mullet are described as having the back very clear carmine red, without any yellow between it and the silvery colour on the belly. If, therefore, colour is to be depended on in these fishes, Mr. Couch's two specimens appear to have belonged to a species different

from either the common striped, which is so well known on our coast, or from the plain red as described from the specimens found in the Mediterranean and in the Black Sea, in which it appears the red species is also known. These circumstances tend to continue the confusion which certainly at one time existed respecting the species of these much-celebrated fishes, and we must regard it as still a doubtful question, whether a red mullet, identified with the plain red mullet of the south of Europe, has ever yet been actually met with in the British seas. The notice by Pennant of one found on the Scottish shores is only a hearsay notice; and as the striped mullet is a mere straggler, if known at all on those shores, and as no drawing was made of that to which Pennant alludes, it is at least possible that it may have been a straggler of the striped kind; and, as a new fish, it was not unnatural to refer it to that species which is regarded as having the greatest celebrity.

The mullet most common on the south coasts of England, though it does not altogether quit those coasts at any season, is a little capricious even at those times when it is most abundant; for, after the fishermen have had a successful fishing for some time, they occasionally find that not a single fish remains upon the ground, even long before the proper season is over. When this occurs they have to try for the shoal of fish eastward or westward, according to circumstances, but seldom much further out to sea in one situation than in another, unless there is a great difference of depth of water and character of the bottom in-shore. This shifting of the fish makes the price very fluctuating; so that in the same season, and within a few days, a mullet shall be so many pence at the one time, and as many shillings at the other.

MUNDIA (Kunth). A genus of greenhouse shrubs, belonging to *Polygalææ*; formerly the *Polygala spinosa* and *viminea* of botanical authors. Both flowers and fruit are beautiful, and the plants are easily cultivated.

MURACUIA (Jussieu). Beautiful ornamental climbers from tropical America, belonging to *Passiflorææ*. *M. ocellata* is one of the most desirable climbers for a hothouse, as it grows freely and flowers abundantly. The flowers are crimson, and extremely showy. It requires a rich light soil, and may be increased by cuttings.

MURALTIA (Necker). A genus of evergreen shrubs, natives of the Cape of Good Hope, belonging to *Polygalææ*. They are pretty greenhouse shrubs, and easily kept and propagated.

MURRAYA (Konig). Evergreen shrubs, natives of China and the East Indies. The flowers are deciduous, and belong to the natural order *Aurantiacææ*. They may be kept in the greenhouse, but flower best in the stove; they affect a light turfy loam, and are readily increased by cuttings.

MUSA (Linnæus). A genus of the largest herbaceous plants known. Their organisation and inflorescence are so peculiar that the genus gives a title to a natural order, viz. —

MUSACEÆ. This, though a small natural order, contains some of the most conspicuous plants in the world. There are only four genera, viz., *Musa*, *Urania*, *Strelitzia*, and *Heliconia*. Of these there are already twenty-eight species described. The most stately, as well as the most useful of these plants, is the *Musa paradisiaca* and *sapientum*, extensively cultivated in the East and West Indies for their fruit.

These have been long in Britain, and frequently fruited in hothouses lofty enough to allow their full growth. In the West Indies the banana is indispensable; shady walks of them are on every plantation, and attached to every house and cottage in Jamaica. As the banana is perennial, and ever throwing up a succession of young stems, some one or other of the plants are yielding fruit the whole year round, and this is very often the chief part of the food of the owner and family. Three dozens of the fruit are sufficient to serve one man a whole week instead of bread, and will support him in warm countries much better. When boiled or roasted they are used in the place of bread, and eaten with fish or salt meat. When ripe, tarts are made of them, or the fruit is sliced and fried with butter, or dried and preserved as a sweet-meat, or converted into an excellent marmalade. The young shoots are eaten as a delicate vegetable, and the old stems, when shredded or chopped up, are excellent manger-food for cattle.

The fruits of some species of *Heliconia* and *Urania* are also eatable, but they are inferior to the bananas. *Musa textilis* affords a very valuable flax-like fibre, from which some of the finest India muslins are made. The *Strelitzia regina*, named in honour of queen Charlotte of England, is a beautiful flowering plant, and much valued. The flowers of all the genera are pentandrous, except *Urania*, which belongs to the sixth class of Linnæan botany.

MUSCA (Linnæus). Under this name Linnæus comprehended a great variety of dipterous insects, which, from the vast accession made to their numbers by modern entomologists, and by the more precise investigation of their characters, it has been found necessary to separate into several families, and a vast number of genera; of these the greater part compose the family *Muscidæ* of Leach, or the tribe *Muscides* of Latreille, which are characterised by having the proboscis membranaceous, of moderate size, and terminated by two fleshy lips generally furnished with a pair of palpi, and capable of being withdrawn into the oral cavity; the antennæ are terminated by a large, often triangular-shaped, joint, having a basal or lateral bristle; the wings are provided with but few nervures. The works of Meigen, Fabricius, Fallen, and especially Macquart and Robineau des Voidy, must be consulted for a knowledge of the great number of species and genera of which this group is composed, and of which some idea may be obtained from the fact that the work of the last-named author extends to about 800 quarto pages, and comprises technical descriptions of a portion only of these insects, and in the work of Meigen, upon the European species alone, the genus *Tachina* comprises 315 species, and that of *Anthomyia* 230.

These insects are best typified by the common domestic fly, the blow-fly, bluebottle-fly, &c. These insects frequent houses, outhouses, woods, hedges, ditches, ways, water-courses; in fact they may be said to be found everywhere. They fly with lightness and rapidity, and make a buzzing noise whilst on the wing. Many species are exceedingly troublesome, especially those which frequent our houses; they are found abundantly throughout the summer, and especially in July and August; they alight upon all sorts of food, especially sugar and sweetened materials, which they much prefer, and which they sip with avidity.

Busy, curious, thirsty fly,
Drink with me, and drink as I,

is a distich too well known from childhood to render it necessary for us to remind the reader of the apparent delight which flies have in sipping up a drop of spilled wine; but the fly is equally able to sip up a bit of sugar, which it effects by first moistening it. Many species delight in decaying vegetable or animal matter; indeed they may be considered as commencing the work of scavengers, by depositing their eggs or young upon matter just on the point of "truning" or becoming putrid. Of their powers in this respect some idea may be obtained from the statement of Linnæus, that three flesh-flies will devour a dead carcass as soon as a lion. Of course, the progeny of the flies and their great powers of multiplication must be taken into the consideration.

Amongst these insects the *Musca* (*Anthomyia*) *meteorica* is one of the most annoying; it is this species which appears about the middle of summer flying in swarms about the heads of horses and cows, and endeavouring to creep into their eyes and ears, in order to feast upon the humours secreted by those organs, not only in the quadrupeds above mentioned, but also of man himself. The *M. domestica* is another exceedingly abundant species frequenting our houses, but there are many distinct species which have precisely similar habits, and which it requires some examination to distinguish from the common species. Certain species of house-flies indeed seem to frequent particular localities, for during the present summer and autumn (1836) we have been examining these insects rather attentively, and have not yet seen a single stomoxys in our study, whereas on paying a visit to a friend at the commencement of this month (September), at some distance from the metropolis, we found the stomoxys swarming in his apartments. Our recent investigations have been conducted with a view to clear up an inquiry proposed to us by Dr. Thaddeus W. Harris, librarian of Harwarden University, United States, as to the specific identity of the domestic flies of Europe and America. We have, it is true, not yet been able to ascertain this point; but from observations communicated to us by Mr. R. H. Lewis, M. E. S., relative to the swarms of house-flies on board the vessel in which he sailed recently to New South Wales, which bred in the ship, it is evident that America may have been as practically tenanted by our domestic fly as by the hive-bee, which is now completely domesticated there. There is, however, scarcely any other insect which could be mentioned which more strikingly exhibits our ignorance of the habits of even the most common insects than the house-fly. We know its general form, and that it is exceedingly abundant, but beyond this our knowledge can scarcely be said to extend.

We have already, in the articles upon the *BLUENOTTLE* and *BLOW-FLY*, given an account of two of the most common, but not the least interesting, species of the present family; and in the article *DIPTERA* we have noticed the question which has excited so much attention amongst philosophers as to the means whereby the fly is able to walk upon glass in a perpendicular position, or even with its back downwards.

The larvæ of the *Muscidæ* (whereof we have given a representation, in the article *INSECT*, p. 835, fig. 19) are thick, fleshy, cylindric, attenuated towards the head, and truncated at the other extremity of the

body; the head is soft, with two or three horny points, which serve to pierce the matters upon which they feed; they are also provided with spiracles, whereof the number and figure are variable, some being placed upon the head, resembling eyes, and the others, which are larger, placed at the posterior part of the body. They are destitute of legs, and their progression is effected by the hooks of the mouth, which they affix in the surface of the substance upon which they are placed; having first extended the body as far as possible, they then draw the hind parts of the body towards the head, contracting it as much as possible, when they again push the head forward as before. These larvæ feed upon various matters, both animal and vegetable; amongst the herbivorous species, many devour decaying fungi, boleti, &c., the galls and seeds of plants, and the interior of fruits; amongst the carnivorous species, some prey upon the flesh of animals, of which they cause the more rapid decomposition, whilst others live in excrement, manure heaps, &c., and some are parasitic, living in the bodies of other caterpillars, of which they devour all the inner parts. The curious manner in which these larvæ assume the pupa state, without throwing off the outer skin of the larva, has been described under the article DIPTERA. The pupa state is variable in its duration according to the state of the weather, which may be more or less favourable to the development of the different parts of the enclosed pupa. In order to effect its escape from the pupa, the fly bursts off a small cap at one end of the case or skin-cocoon by beating against it with its head; at first these flies are soft, and may be observed creeping along with their wings crumpled up in a small compass. They soon, however, gain their full size, and the fly acquires its dark colour, and then joins its companions in the air.

Latreille has divided this family into nine primary groups, from various peculiarities of structure; whilst Macquart, availing himself of the researches of M. Robineau des Voidy, has partially adopted the habits of the groups for the establishment of three subfamilies, in which he traces a gradual decrease in the organisation of these insects until his arrival at the confines of insect life.

1. The *Creophila*, characterised especially by the wings, of which the first posterior cell is entirely or partially closed, and by the large size of the alulets. This subfamily comprises those species which are distinguished by their size, colours, robustness of body, strength of flight, &c. They generally deposit their eggs either upon the flesh of dead animals, or are parasitic in the bodies of other larvæ. The chief genera are *Tachina*, *Ocyptera*, *Gymnosoma*, *Phasia*, *Deria*, *Sarcophaga*, and *Musca*.

2. The *Anthomyzides*, distinguished from the preceding by having the first posterior cell constantly open, and by the moderate or small size of the alulets. They chiefly frequent flowers; and their larvæ reside in decomposed vegetable matters. The chief genera are *Aricia*, *Lispe*, *Eriphia*, *Anthomyia*, *Cænosis*, &c.

3. The *Acalyptera*, differing from the *Anthomyzides* by the breadth of the face, in which the eyes of both sexes are separated, and by the want of alulets. Here belong various groups of small size and inferiorly developed structure, which are for the most part exceedingly prolific. The chief genera are *Lorocera*, *Scatomyza*, *Ortalis*, *Tephritis*, *Sepsis*, *Lauzania*, *Sphærocera*, *Phora*.

The genus *Musca* is now restricted to the domestic

fly (*M. domestica*) and a few allied species, instead of comprising, as it did with Linnæus, the entire dipterous order, with the exception of the *Tipulidæ*, *Tabanidæ*, *Asilidæ*, *Bombyliidæ*, and *Empidæ*. We have here the two extremes of classificational nomenclature, evidencing the progressive elaboration of insect investigation, but unfortunately, although necessarily, attended with so great an addition of names as to become far beyond the powers of ordinary memories to retain them throughout the science. Hence the necessity of reverting to the old well-established names in the sense in which they were formerly employed for general purposes, but at the same time of employing the newly-required terms for scientific and particular purposes.

The type of the genus *Musca* (*M. domestica*, Linnæus) is of a cinereous colour; the face black, with buff sides; the forehead yellowish, with a black band; the antennæ black; the thorax with black lines; the abdomen with black markings, pale beneath, the sides of a transparent yellow; the legs black; the wings clear, with the base rather yellowish.

MUSCARI (Desfontaines). A genus of bulbous plants, formerly united with the hyacinths. The flowers are hexandrious, and belong to *Asphodelææ*. The well-known grape-hyacinths are *Muscari*; and the *Hyacinthus monstrosus* is now *Muscari comosum*. They are flower-border plants, and thrive in light sandy soil.

MUSHROOM is the *Agaricus campestris* of Linnæus, the eatable agaric. Though a cryptogamous plant, and, as such, not coming within the limits of our general botanical notices, yet as a dietetic vegetable, and as a production requiring much skill and attention of the gardener, it may be worth while only to remark, that the mushroom is the only instance of any of its class having been brought into cultivation. The champignon, the truffle, and morel, are three others used in cookery, but these have not been as yet tried to be produced artificially; nor with the two last is cultivation necessary, as they are never used in a fresh state.

MUSK (*Moschus*). A genus of ruminant mammalia, or, more strictly speaking, a small and very peculiar group, made up of two genera; the one consisting of only a single species, and furnishing the substance known by the name of musk; the other consisting of several species, much smaller in size and more elegant in form than the other one, but not provided with the organ which secretes musk, and consequently not supplying that substance. In their general structure the musks do not differ greatly from the other hoofed ruminants, though they still hold a sort of intermediate place between them and the camels. The chief external differences are, the absence of horns, and the very much produced canine teeth in the upper jaws of many of the males. These last project out of the closed mouth, and are usually recurved backwards. In the skeleton the chief difference consists of a fibula applied to the head of the tibia on the hind legs, and extending down nearly to the lower extremity of the bone; and there is no bone of this kind found in any of the other ruminants except the camels. They have farther two small bones, applied one to each end of the canon bone on the fore legs, more developed in proportion than those bones in the horse, and answering in situation, though not in office, to a sort of ulna. As none of these additional bones extend completely from joint

to joint, they do not assist in giving any cross or twisting motions to the joints, which are still susceptible of vigorous motion only in one plane, like the corresponding joints of the other ruminants. Still these bones are by no means without their use in the economy of the animals, for they give a firm insertion and imbedment to the muscles, and also a security against fracture, which could not be secured by any single bone, how much soever it might be beset with processes. The cartilaginous union between those bones and the others, prevents the shock upon the principal bone of the limb from being propagated to the muscles, and jarring and disturbing their action, at the same time that it gives strength and firmness to the muscles and tendons, by means of which they can better bear their part in the motion of the limb.

And when we come to consider the camels, and more especially the musks, and, most of all, the animal which furnishes the perfume, in combination with the peculiar nature of their pastures, we cannot fail to be struck with the admirable resource of nature in furnishing their limbs with means of endurance in proportion to their size, which are not to be met with in any other animals having merely walking feet. It is true that the small bones applied to the canon bones of the horse give great additional stability and power of endurance to that animal; and it is, in a great measure, in consequence of the possession of these small bones, that, as it is beautifully expressed, the horse "paweth in the valley and rejoiceth in his strength." It is in the *valley*, however, that the horse shows off his fine paces—upon the turf, where there is still some elasticity in the covering of the ground, which helps to let him down gently as he dashes along. With the camel and the musk it is different. The march of the camel is in the *desert* and often deep in the sand, so that he is necessitated to lift his feet high, and consequently make a bumping and heavy foot-fall, which would shake the legs of a differently constructed animal to pieces. The musk has still severer pastures; he is on the dry and rocky mountains, where it seldom rains, and where mouthfuls of food are "few and far between," and therefore nature has adapted his limbs to the wilderness of stones as finely as the limbs of the camels are adapted to the wilderness of sand. It is in those creatures which are fitted for what may be regarded as the extremes of locality that we see most forcibly the admirable provision which nature, that is, the Great Author of nature, has made for every creature according to its necessity.

As the animal which produces the musk, and the other animals which nearly agree with it in general structure, are brought into the same group, have different localities, both in latitude and in character of surface, they necessarily have different adaptations, and therefore a description, descending to much minutiae, could not apply properly to them both. It is true that they are all upland or mountain animals, fitted for bounding along in dry places; and the small ones are admirable in the delicately light appearance of their bodies and limbs, and most graceful in their motions. But they are children of the lands of the sun, and not more than one is found out of the Oriental Archipelago, and even that one is rarely, if at all, found as far north as the central latitude of India. We shall therefore take them separately—the one that has been longest known, under the generic name *Moschus*; and the others under the generic name *Tragulus*.

MOSCHUS. The species of this genus is the common musk (*Moschus moschiferus*), whose head-quarters are in the vast table land of Central Asia, between the sources of the Indian rivers in the south, and those of the great Siberian rivers in the north; and between the sources of the great Chinese rivers on the east, and the rivers which flow to the inland seas of Asia on the west. These rivers do not overlay each other, as is the case with the rivers which rise in single ridges of mountains, or upon successive ridges where much rain falls. The remote sources of some of them, indeed of most of them, are very imperfectly known; for few portions of the earth's surface are more completely a sealed book to the natural geographer than this same portion of Asia; but we are sure that there is in the centre of this extensive region a very large portion from which no river is discharged; and it is this portion which forms the grand abode, and in some respects the fortress, of the musk animal. That animal is thus intimately connected with one of the most interesting questions which remain unsolved respecting the natural history of the earth's surface; and, besides this, the most characteristic animal of such a country is highly interesting on its own account; and the interest is certainly not lessened by the perfume which the animal furnishes, and the great estimation in which this perfume is held, more especially in the East.

The animal is not confined to the absolute centre of this table land, but extends along the mountain ridges which branch out from it. It is not found to the southward of the Himalaya, nor in the central desert which slopes westward to Lake Aral and the Caspian; but it extends south-eastward into the elevated parts of Tonquin, and northward as far as the Altaian ridge. Those nations, speaking many languages, are familiar with it; and there is not, perhaps, throughout the world an undomesticated animal which has more names than the musk.

In such an extent of latitude as it inhabits, it is natural to suppose that it must be affected by some climatal differences; but it does not appear that these are such as to affect the identity of the species. The chief difference is in the odour of the drug, which is more powerful in proportion as the animal inhabits more southerly. In the warm latitude of Tonquin it is exceedingly powerful, while in the extreme north of the animal's habitat it has not more odour than the substance furnished by the beaver in polar climates.

Musk, as a substance, was known in Asia from very remote antiquity; and it was very early introduced into Europe. It was long, however, before any knowledge was attained of the animal producing it, and some of the earliest accounts represented the animal as a deer with horns. Our illustrious countryman Grew, to whom natural history generally, and particularly the physiology of plants, is so much indebted, was the first naturalist who gave anything like a satisfactory description of the animal, and Buffon and Daubenton were the first who obtained a living specimen in Europe, while Professor Pallas had opportunities of examining the animal in its native locality. After this it speedily took its place in the system, as a distinct and very peculiar ruminant animal.

When full grown it is about the size of a roebuck at six months old, being one foot ten inches in height at the shoulder and two feet at the crupper. This superior production of the hind legs indicates a vigorous

leaper; while the disproportion is not so great as to destroy the symmetry and power of its action as an animal of swift motion on its legs. The upper part of its head bears some resemblance to that of a roe-deer; but the character of the mouth is different, arising not so much from the form of the bones as from the large canines which descend from each side of the mouth, and make the upper lip seem broad; and the tufts of produced hair at the bottom of the gape give an appearance of breadth there also. The hair is remarkably coarse and strong, and has almost a spinous appearance. The basal part of it is white; but the extremities are different shades of black, brown, or dun colour, which makes the general tint vary with the position in which the animal is seen. The under part of the body, the insides of the legs, the chin and the lips, are white; and the eyes are reddish brown. The legs, though clean and light, are very firm; and the hoofs are strong and sharp-pointed. The successorial, or supplemental hoofs behind the principal ones, are much longer and firmer in proportion than those of any other ruminating animal; and though they cannot be said to act against the others by an absolute grasp, as a thumb acts against fingers, yet they enable the animal to take a firm hold of the sharp edges of those rocks among which it has so frequently to make its way; and thus furnished in its feet, the animal can ascend and descend with equal rapidity and safety as the chamois. In fact no animal is better adapted for bounding from rock to rock, clearing chasms, mounting precipices, and descending the steepest slopes. It is also an excellent swimmer, and can stem the torrents of the mountain streams with the greatest hardihood.

Inhabiting a country where it is subjected to many privations, it can, during the severe weather, subsist upon lichens, like the rein-deer; and in the summer it is under the necessity of browsing the leaves, and even gnawing the stems of those rhododendrons, which form the principal vegetation of some of its more northerly haunts. In short it is an animal tempered to a hard country, to hard weather, and to hard food. Notwithstanding the comparative sterility of their pastures they become very fat in the autumn; and in proportion as they become fat the musky secretion becomes abundant and odorous. Whatever may be the purpose of this secretion, the matter of it seems to pervade the whole animal; for even the chyme, before it is converted into chyle, has a musky smell; and the flesh of the animal has the same, and the stronger the higher condition it is in. The natives of the country hunt it with considerable avidity as well for the musk as for the flesh of the animal. The little pouch which contains the musk, and the follicle by which it is secreted, are peculiar to the male, and situated backwards on the abdomen. Various physiological theories of the use of this substance has been propounded, but none of them is altogether satisfactory; and some of them, together with inferences which have been drawn from them, do not admit of satisfactory explanation in a popular manner.

These animals come in season in November; and the fawns are dropped about the end of May. Their colour is at first reddish grey, dappled with whitish spots disposed in lines. In the following winter they become deeper brown, with yellowish spots irregularly disposed on the flanks, and more regular ones on the back. The produced canines of the

males are not developed until the animals arrive at maturity.

The time for hunting the musks is chiefly in the rutting season; that is, in November; because then, as we have already hinted, the musk is most abundant and has the most powerful scent. When the animal is seized, which is rarely done without killing it, as they are very timid as well as very fleet, the first care of the hunter is to secure the musk-bag, which is done by cutting it out and rolling it up like a little purse; the quantity contained in one is very small, however; and therefore it is generally understood that even the best musk of commerce is adulterated by being mixed with other substances. Some differences of species as to size and colour, and the form of the ears, have been mentioned; but probably these are merely climatal; and they do not appear, from the accounts given of them, to be accompanied by any differences in the economy of the animals.

The musk animal never descends into the plains, or approaches the habitation of man. It is decidedly an animal of wild nature, endeavouring to escape to its fastnesses when seen, and incapable of anything like domestication.

TRAGULUS. This name, taken literally, means "little goat," or, in fact, any small animal with a rough or shaggy coat, which browses hard plants, and gnaws the twigs or the bark of trees; and it has been sometimes applied to one section of the antelopes, which are remarkable for the length, height, and fleetness of their leaps.

The generic characters of the small animals to which this name is applied differ very little from those of the musk animal properly so called, only they are all without the musk-bag and follicle, and thus are not musk animals in any other sense than as they belong, in their general structure, to the same group with the animal that furnishes the drug. All the animals which are included in this genus or subgenus are inhabitants of the mountain forests, or, at all events, of the forests upon elevated places; but their haunts are too difficult to be explored for enabling us to speak positively as to the species. There may be distinct species which are not at present known; and some of those which are now described as species may be only varieties; we must, however, take them according to the accounts given by those who have seen them on the spot.

Memina (T. memina). This animal is about the size of a rabbit, that is to say, sixteen or seventeen inches long, with a very short tail; the covering on the upper part is olive-ash; and the throat, breast, and belly, white; the neck, sides, and horns, are also peculiarly, but not unhandsomely, marked with lines and bars of white; there are two longitudinal ones upon each side; one near the back, which terminates in a turned-up point at the hinder part of the loins; the other is broader, farther down, and more irregular; but whether these are uniform in all individuals, or at all ages, is not ascertained; the ears are rather large, and the muzzle produced and slender; the canines in the male are large for the size of the animal, and much recurved backwards.

The memina is the species of these little musks which has been longest known. It was first mentioned by Knox, in his account of Ceylon, as a native of that island; and it has since been found in the southern part of continental India. In the account of the mammalia of the Deccan, laid before the

Zoological Society of London in 1831, this animal is represented as being numerous in the woods of the Western Ghats, but it does not descend into the low country toward the coast. The Mahrattas call it *Pesoreh*. So far as has hitherto been observed, it is the only one that occurs on the continent of Asia, and it is not found far to the north. The others have been met with chiefly in Java, but they in all probability inhabit the adjacent islands.

The *Napu* (*T. napu*) is the largest of the Javanese species. It is about twenty inches long and rather more than a foot in height, standing higher at the rump than the shoulder. The upper part is mottled red colour; the sides grey, marked with white, and the under part and insides of the legs altogether white; the tail is about two inches and a half, white on the under side and at the end, which is furnished with a small tuft of produced hairs; it is also variously striped with white and grey; the legs are very slender, and the body rather heavy, which gives the whole an air of feebleness and incapacity for violent exertion. It inhabits lower down than the memina, being met with in the low thickets, and not in the elevated woods.

The *Kanchil* (*T. Javanicus*) has some general resemblance to the *Napu* in the form of its body, but it is more lightly and handsomely made, much smaller in size, and very different in colour. It is only from fourteen to fifteen inches in length, and about nine in the average height. On the middle of the back it is very dark brown, approaching to black, but this passes gradually into bright bay on the sides, while the belly and insides of the legs are white. Like the *Napu*, this species is marked with white streaks on the breast, but they are differently disposed. The variations of colour and size are constant, and moreover the habits and manners of the two animals do not agree. These, together with the different names given to them by the natives, are sufficient grounds for regarding them as distinct species. The *Kanchil* is an inhabitant of the dense forests, and much more mild in its disposition than the *Napu*. If taken young, the *Napu* can be tamed without much difficulty; but the *Kanchil*, though not a vicious animal, cannot be tamed, and escapes to the forest whenever it can find an opportunity. Living in the forests, which are infested with powerful carnivorous animals, this active little creature has occasion for no slight degree of cunning and resource in order that it may preserve itself from them. Nor is this animal found without sufficient means of self-protection in proportion to the danger in which it is placed. It is very quick, and equally cunning. If it is free, so that it can avail itself of its active powers of escaping, and is hard pressed in the chase, it is said to make a vigorous bound upward, catch a branch with its strong and hooked canines, hang suspended there while the enemy passes underneath, and, as soon as the ground is clear, jerk itself down, and make off in the opposite direction. If it has no active means of escape, its passive cunning is equally great. It is well known that many animals attempt to follow the pattern of the "passive stout," mentioned by Butler, and

"Run away from death by dying."

Foxes have been known to do this when surprised in a poultry-house from which they could not make their escape; and the dead fox, after being taken by the hind legs and tossed out as lumber, until there

should be time for making him pay the forfeit of his skin, has been known to start instantly, and bear his brush triumphantly to his cover. The *Kanchil* is said to practise a similar ruse when caught in nooses. It lies stretched, and looking as if strangled; but if the hunter undoes the noose, the *Kanchil* vanishes in an instant.

The *Pelandok* (*T. pelandok*) is described as being lower on the legs and heavier in the body than the *Kanchil*, and, though resembling the *Napu*, a more sluggish animal in appearance than even that. Its colour on the upper part is light rusty grey; the canines were very small in the specimens seen, which renders it probable that they were immature animals, in all probability, of the *Napu*, or, at all events, closely allied to it. The habits are said to be exactly the same as that animal, brushwood, in the neighbourhood of houses where predatory animals are comparatively few, being preferred to the wild woods, in which the lighter but more energetic and spirited *Kanchil* invariably takes up its residence. Information is, however, still wanted respecting these animals.

MUSQUITO. The name of one of the most tormenting of our insect enemies, which, from the attacks of its countless multitudes upon sleeping persons, is the subject of more consternation and alarm than can well be imagined by persons who have never encountered them. In our country the bite of the gnat is regarded as an evil, but in the sultry climates of Brazil, India, &c., where, from the exhaustion attendant upon the daily heat, the body has need of sound nightly rest, the attacks of the musquito become a real plague, and one of the greatest luxuries that can be imagined is a musquito-proof curtained bed. Like the gnat, the musquito announces its approach by a buzzing hum; and it is one of the most particular duties of the attendants of the inhabitants of these countries to whisk away the musquitoes which, during the day, have taken shelter within the bed-curtains, by means of a flapper, and then suddenly to let fall the curtains, which are provided with weights at the edges; and the ceremony of lifting up the curtains and jumping into bed must be performed as quickly and as carefully as possible, to prevent the ingress of the fearful plague. The gnats and musquitoes belong to the same natural group, *Culicidae*, and as they breed in stagnant water and damp situations, it does not seem improbable that the last-named insects were the species of flies which were employed as one of the ten plagues of Egypt to punish the rebellious Egyptians. In the article *BAR* there is the following passage, which especially bears upon the subject: "The banks of the Nile, in Egypt, where they (the bats) dwell in the palaces and sepulchres of forgotten kings, and the temples of forgotten gods, are particularly replenished with them, because the swelling and subsiding of the Nile cause a vast production of insect life." Mr. Kirby, indeed, adopts another opinion, suggested to him by an eminent and learned prelate, that the Egyptian plague of flies, which is usually supposed to have been either a mixture of different species, or a fly then called the dog-fly (*κυνόμυια*), but which is not now known, was a cock-roach, the Hebrew name of the latter, which is the same by which the raven is also distinguished, furnishing no slight argument in favour of it, the same word also signifying the evening. Hence, as the cock-roach of Egypt is black, and appears only in the evening, Mr. Kirby

considers the reason sufficient for the name given to it. We are afraid of being charged with presumption in venturing to differ from these learned divines on a point of biblical natural history, but we cannot avoid adopting the opinion that the plague of flies was caused by the mosquito. Mr. Kirby evidently appears to have previously adopted the view of the subject given by Bishop Patrick, who says of these flies, that they were "flesh-flies or dog-flies, very bold, troublesome, and venomous. Some think the Hebrew word means a mixture of different insects, all manner of flies;" and Bruce regards it as being probably identical with the insect which he describes under the name of the zimb. We read, on the denunciation of this plague, that Moses was directed to say to Pharaoh, "If thou wilt not let my people go, behold I will send swarms of flies upon thee and upon thy servants, and upon thy people, and into thy houses; and the houses of the Egyptians shall be full of swarms of flies, and also the ground whereon they are; and I will sever in that day the Land of Goshen, in which my people dwell, that no swarms of flies shall be there;" &c. Now in this passage we are first struck with the expression "*swarms of flies*," and we are sure that every one who has seen "a swarm of gnats at even-tide" will perceive the aptness of the expression, supposing the Egyptian fly be a species of gnat, or, in other words, the mosquito. We next read of their making their way into the houses, which shall be full of flies. This is also precisely the habit of the *Culicidæ*. The next passage, that they should also swarm upon the ground, is certainly not in favour of our interpretation, and would apparently apply to some other species; but it is in the last passage quoted that we perceive the fullest corroboration of our view of the subject. Bryant says, "The Land of Goshen was a tongue-like piece of land, where the Nile first divided at a place called Cercasora; Said, or Upper Egypt, lying above, and Mesre, or Lower Egypt, was in a line downward;" and Bruce states, that "the Land of Goshen was a land of pasture, not tilled or sown, because it was not overflowed by the Nile. But the land overflowed by the Nile was the black earth of the Valley of Egypt, and it was here that God confined the flies, for He says, it shall be a sign of this separation of the people which He then made, that not one fly should be seen in the sand or pasture-ground of the Land of Goshen; and this kind of soil has ever since been the refuge of all cattle emigrating from the black earth to the lower part of Atbara." These observations appear to the writer almost conclusive upon the question: the sandy pasture soil of the Land of Goshen would have been the spot where the cock-roach would have resorted to naturally, and it is the spot where the mosquito would not have been found. Far be it from us to deny the miraculous power of the Almighty in producing this surprising flight of flies, but we know, in our own days, that in certain seasons certain species of insects are multiplied to such an extent as to become a positive evil. We know not, of course, for what end such multiplication is permitted by the Creator; but in the one case, as well as in the other, we must certainly acknowledge the working of an all-wise Providence, which sees and understands what man cannot comprehend.

We are aware that Dr. Hale and Bryant have given calculations, whereby it would appear that this succession of plagues took place between the month

of January and the beginning of April, and consequently that the plague of flies, &c., must have been miraculous, occurring at a season when the Nile was at its lowest, and when flies, &c., were not naturally abundant; but there is nothing fully to warrant the adoption of a fixed period of time between the early plagues.

We have said that the mosquito is a species of gnat (*Culicidæ*), nearly allied to our common English species, *C. pipiens*. In making this statement we have followed the best authorities. Mr. Kirby says that the mosquito from Batavia, whose bite is exceedingly venomous, occasioning a most intolerable itching, which lasts several days, is distinct from the common gnat, and approaches *C. annulata*, but the wings are black, and not spotted. Robineau des Voids and M. Percheron have described and figured the insect under the name of *Culex musquito*; and Pohl and Kollar have described the Brazilian mosquito, as it is termed by the Portuguese, under the name of *Culex molestus*.

Of the attacks of these insects we can obtain, from the accounts of various travellers, the most striking idea; thus Jackson, in his Travels in Morocco, complains that they would not suffer him to rest; that his face and hands appeared, from their bites, as if he was infected with the small-pox in the worst stage. And Captain Steadman, in his Travels in America, states that he and his soldiers were actually compelled to sleep with their heads thrust into holes made in the earth with their bayonets, and their necks wrapped round with their hammocks. But it is in the chronicles of the olden time that we find the most extraordinary account of their powers; thus it is related that a king of Persia was compelled to raise the siege of Nisibis by a plague of gnats, which, attacking his elephants and beasts of burden, caused the rout of his army. And Mouffet has collected many accounts from different authors, in which it is recorded that the inhabitants of various cities have been compelled to desert them owing to the multiplication of this plague, which has become so notorious as to give its name to bays, towns, and even territories of considerable extent. Thus we have Musquito Bay, in St. Christopher's; Musquitos, a town in the island of Cuba; and the Musquito Country, in North America; as stated by Kirby and Spence.

The name mosquito, therefore, appears to be applied to any species of *Culicidæ* tormenting to mankind in foreign countries. It has also been applied to some minute midges belonging to the genus *Simulium*, and family *Tipulidæ*, but which are distinguished from the preceding, in North America, as the writer is informed by a competent entomologist, by the name of the black-fly.—See *SIMULIUM*.

MUSSÆNDA (Linnæus). A genus of evergreen shrubs, natives of both Indies, belonging to *Rubiaceæ*. Generic character:—calyx irregularly five cleft; corolla funnel-shaped, limb spreading, and five-parted; anthers sitting, included in the tube of the corolla; style simple; stigma bifid; capsule two-celled, with transverse dissepiments. These are pretty plants, thrive in loam and moor-earth, and are propagated by cuttings.

MUSTARD is the *Sinapis nigra* of Tournefort, a well-known economical British plant.

MUTILLIDÆ (Latreille). A family of fossorial aculeated *Hymenoptera*, in which the females are generally destitute of wings, the males being winged; hence Latreille has placed this family in the sub-section *Heterogyna* with the ants, but their economy

is identical with the fossorial or burrowing sand-wasps, from which they are alone chiefly separated by the apterous condition of the female; the antennæ are filiform or setaceous, vibratile, with the first and third joint elongated; the basal joint is not, however, so long as to form with the following joints an elbow at its extremity. The family is composed of the Linnean genus *Mutilla*, which has been divided into several modern genera, viz., *Douglas*, *Labidus*, *Apterogyna*, *Psammotherma*, *Myrmosa*, *Myrmecodes*, and *Methoca*. The genus *Mutilla* is distinguished by having the antennæ inserted in the middle of the face; the abdomen ovoid, the thorax continuous in the females, and the antennæ in the males simple. There are many exotic species of this handsome group, two or three of which alone are inhabitants of this country, including the typical species *Mutilla Europæa*, Linnæus, which is of a bluish-black colour, with the thorax red, and with three white bands across the abdomen; the male is winged. The writer of this article has repeatedly taken it in sandy situations in Coombe Wood, the female being found only on the ground, running very quickly, and endeavouring to conceal itself with much cunning on the approach of danger.

MYA (Lamarck, Linnæus). These molluscs are marine bivalves, transverse, not always equivalve, gaping at the two ends, one of which is usually truncated obtusely. The hinge presents a very singular, large, compressed, spoon-shaped appendage, rising perpendicularly from the plane of the left valve, and fitting into the entrance of the primary corresponding cavity on the opposite valve, when both are closed; the ligament is interior, short, thick, and attached to the projecting tooth on one side, and to the cavity on the other. These molluscs lie concealed at various depths on the sandy shores, and protrude a long membranous tube, enveloping two smaller ones, to the surface. Some fossil species have been discovered, but they are by no means common.

MYCETOPHAGUS (Fabricius). A genus of coleopterous insects, belonging to the family *Engidæ*, according to Stephens, but placed by Latreille in his unnatural family *Xylophaga*, having the club of the antennæ composed of five separate joints, the body ovate, sub-depressed, the legs of moderate length, and the tarsi four-jointed, the males having only three joints in the anterior pair; the species are of small size, and frequent fungi, rotten trees, &c. There are six British species, the type being the *Chrysomela 4-pustulata*, Linnæus, which is a quarter of an inch long, of a reddish colour, with the thorax and elytra black, the latter with four red spots.

MYGALE—Musk Rat. A genus of insectivorous mammalia, approaching more nearly to the shrews than to any other family; and yet differing sufficiently from them to warrant its being constituted into a different genus. It differs from them in its dentition, by having three small teeth placed between the two large incisors in the lower jaw, and by having the two incisors in the upper jaw triangular and flat. Behind the incisors there are six or seven small teeth, and four cheek teeth, having their crowns thickly beset with sharp insectivorous points. The muzzle is elongated, a little enlarged at the extremity, and the animal keeps continually moving it. The tail is very long, flattened laterally, and covered with scales; the feet have five toes upon each, all united by membranes; the eyes are exceedingly small; and

there are no external ears. The whole structure of the animals indicates an aquatic habit; and they are accordingly found lodging on the banks of streams and stagnant waters, and seeking their food in the water itself, or capturing those insects which are usually found in great numbers by the margins of still waters.

The true character of this animal was for a long time misunderstood, some considering it as belonging to the rats, and others as belonging to the beavers; and it is on account of this early error that it is still popularly called the musk rat. It is not, however, in the least allied either to the rats or the beavers; for both of these are rodent animals; and this is very distinctly a member of the insectivorous division of the carnassiers; and it may be said to hold pretty nearly the same rank among that division as the otter holds among the carnivora, and to regulate the numbers of insects in those places where the otter regulates the numbers of the finny tribes. Though it can travel a little upon land, it is principally organised for motion in the water; and its adaptation to the water, though of course requiring a different modification of structure, puts one in mind of the adaptation of the mole to motion under the earth. The form of the skull and the number of teeth, the absence of external ears, the smallness of the eye, and some other circumstances, produce a considerable resemblance to the mole as well as to the shrews; but when we come to the organs of motion we immediately see an adaptation to a medium different from that in which the mole has to perform its labours: the limbs are, like those of the mole, exceedingly short, and a portion of them is imbedded or concealed within the membranes of the body, as is the case with the swimming paws of the amphibia and the cetacea. The paws turn in a vertical direction with the soles backward, just as in the moles; but then they have more of a rolling motion in the knee and elbow joints; so that the animal can recover or advance them, something after the manner of feathering an oar.

The tail also, from its lateral flattening, its strength and its scales, forms an excellent sculling instrument behind; and altogether the animals are well formed for making their way under water. There are at least two species, one in the north of Europe, and the other in the Pyrenees, and probably also in some other mountainous parts in the south; but as the northern one is the largest, the most interesting, and the best known, we shall direct our few general remarks chiefly to it.

Taking this species as the typical one, it may be said to be the most aquatic of all mammalia which retain the typical form, without any approximation in the posterior part of the body to the form of a fish. It is never found in dry places, nor does it pass from one piece of water to another unless it can find a watercourse, a passage under ground, or one under moist vegetables. It is no lover of turbulent waters or swiftly-flowing streams, but prefers still ponds, the margins of lakes, and especially those places which are subject to periodical inundations. These last are indeed its favourite localities; and one can easily see the reason: when the inundation comes there are many earth-worms and other small animals which seek safety by coming to the surface of the earth; and these form at such times an abundant supply of food for this animal. We can understand from this, by the way, why Russia should be its favourite country above

all other countries in the north of Europe. From the flatness of the surface and the nature of the soil—for flat surfaces which have been several times flooded have their pores so shut up by the deposit of the flood that they become retentive in time, whatever the substratum is.—Russia is more flooded than any other country of the north of Europe; for the other northern countries have diversified surfaces, from which the water runs off. Besides this the winter-fall upon Russia is chiefly snow, not rain. This snow keeps the ground warm as compared with the latitude; and the thaw at the return of the season is rapid, and the water remains on the surface at many places, and where it remains it deposits a new quantity of rich soil. This soil, when the water subsides from it, is highly favourable to the production of worms and ground insects; and consequently Russia becomes, more than any other country, the peculiar pasture of an aquatic feeder upon those worms and other ground animals; and we could name no other region of equal extent on the eastern continent, or indeed anywhere on the surface of the earth, so well adapted for such an animal.

The musk rats, accordingly, choose the margins of such places, where they dig themselves burrows, having the entrance under water, but gradually worked up under ground until they ultimately reach such an elevation as places them above the reach of the highest floodings; for though these floodings, while they last, extend over a considerable breadth of surface, they are never of great depth, in consequence of this very fact of the surface allowing them to run into breadth. These burrows are sometimes worked to the extent of seven or eight yards, including all their windings; but as they are merely lurking-places, and not feeding-grounds like those in which the moles work, heaps of earth are not cast up upon the surface. It is understood that, except in the breeding season, the animals dwell singly in their subterranean abodes; and during that season they are monogamists, or live in single pairs. They do not hibernate in the winter; because, though the land in cold climates is barren at those seasons, the waters are fertile to such animals as can reach the bottom, in consequence of the great numbers of larvæ which they contain: many of the insect tribes, which are exceedingly numerous in those northern latitudes during the summer, being confined to the waters in winter as the only places of safety. There is therefore no necessity for hibernation on the part of the musk rats, which can subsist on those larvæ, any more than there is on the part of the beavers, which at the same season live upon dry sticks. Still there is some occasional inconvenience; for the surface over the burrow, and the surface of the water, sometimes get both so completely frozen over as to be air-tight; and then the animals are in danger of suffocation. If there are any cracks or fissures in the ice they crowd to them, and eagerly thrust their noses upwards to the atmosphere; but it is understood that numbers of them perish every winter from this cause.

At ordinary times they are very peaceable and retiring animals; pursuing their own labours in the waters, without disturbing any creature except those small animals on which they feed. It has been alleged that they feed upon the succulent roots of aquatic plants, as well as upon animal matter; but this mistake appears to have arisen from the confounding of them with rats and other miscellane-

ous feeding rodentia. The insectivorous division of the carnassiers are as animal in their feeding as the carnivorous ones, if, indeed, they are not more so; and as the pastures of these animals are at all seasons well stored with animal matter, they have no occasion to have recourse to vegetable food: and Pallas, who examined great numbers of them, was never able to detect the least vestige of vegetable matter in their stomachs.

These animals have got the epithet musk attached to their names, not in consequence of their being possessed of any specific apparatus for the secretion of musk, but simply because of the very strong musky smell possessed by all parts of their bodies. This is so very powerful as to render their flesh quite unpalatable; and not only so, but even pike, and other voracious fishes which feed upon them, as they often do, acquire so rank a smell of musk as not to be eatable. We shall now briefly notice the two species.

RUSSIAN MUSK RAT (*M. Musconitus*). This species is not very correctly called Russian, because it is found also in Sweden; but Russia is its head-quarters; and the part of Sweden in which it is most abundant has been annexed to Russia since the partition of Europe at the close of the last war. This animal is about the size of the common hedgehog, that is, between eight and nine inches long in the body; and the tail is between six and seven inches. Its covering very much resembles that of the beaver, consisting of long hairs of firm texture and exquisite polish, mixed with close, soft, and delicate fur among the roots which last forms an exceedingly warm covering; and the two together are quite waterproof. The colour on the upper part is brown, paler along the middle of the back, and deepening on the flank; and the under part of the body is silvery white. The skin is very firm, and the fur strong and tenacious, though fine; so that the skin of the animal is held in much esteem by the furriers; and, as the animal is abundant, it is obtained in considerable quantities. The tail is a singular organ. At the base it is compressed laterally; but after a short distance it thickens and becomes cylindrical, beyond which it is again compressed, and the compression increases, while the volume diminishes towards the distal extremity. The compressed parts have of course a very free lateral motion, and but little in the vertical plane, and the cylindrical part has less motion in any one plane, but admits of nearly an equal extent in all. Thus, in consequence of the three parts of which it is made up, the tail of this animal is a very curious working structure. The compressed part at the base acts as a sort of hinge, upon which the whole tail can be moved laterally; while the compressed part nearer the tip can produce lateral motions in any part of its length, and more free and rapid ones toward the extremity, where it becomes thinner in proportion to its breadth. The cylindrical part again admits of the two flat parts being bent at an angle to each other, and also of their being twisted into different planes. In consequence of these compound motions, the tail of the musk rat is one of the most extraordinary mechanical instruments in the whole animal kingdom; and it is one well worthy of being studied by every person who wishes thoroughly to understand mechanical principles.

Though there is a considerable resemblance between the countries in the east of European Russia,

and the adjoining part of Siberia, and also between the west of Russia and the proximate part of Poland, yet Pallas, notwithstanding the zeal and industry of his researches, was never able to meet with the musk rat, either to the east of the Volga, or to the west of the Dnieper. Within these limits in longitude, it does not inhabit very far to the north, not higher than the sixty-sixth degree of latitude, and its chief haunts are upon the river Don and its affluents. The climate of Norway is, however, far milder in high latitudes than that of Russia; and accordingly the animal is there found much farther to the north; not in such numbers, certainly, as in central and southern Russia; but still skins have been imported into Germany by the Swedes; and there is no doubt from some northern part of Sweden.

As this is decidedly the most aquatic of all mammalia which retain in chief part the land type, it is, independently of its mere organs of motion through the water, furnished with additional accommodations, which perhaps no other animal possesses in an equal degree. Its mode of feeding is not to follow its prey through the free waters, and catch it by speed as the otter catches fish, because its food consists of animals so small, that they would not singly repay it for the labour of a chase; and consequently, if it were left to this mode of finding its food, it would have no other alternative but to starve; because an animal even of its moderate size, hunting for insects through a medium of so much resistance as water, could not possibly capture as many insects as would supply the waste occasioned by its labours. Therefore, it is so formed, that it preys at the bottom, and dabbles with its nose in the mud and sludge, something in the same way as a duck. Nor is there any doubt that its produced nose is endowed with very keen senses, both of smelling and of touch. The nostrils, opening like the bells of little French horns, show clearly that it must have a keen sense of smell; and the continual motion of the nose, together with the papillæ with which the naked part of it is beset, show as clearly that it is equally keen in respect of touch. It is perfectly evident, indeed, that these are the only two senses upon which the animal can depend for its food; for the insects in the sludge are of course equally silent and invisible; and therefore, in finding its food, the most essential of all its occupations, it can have little or no dependence upon ears or eyes. It is thus in some sort reduced to the state of the mole; and this is no doubt the reason why, in the form of the cranium, and the general air of the head, it has so much resemblance to that animal, though modified so as to work in a much softer substance.

This habit of the musk rat, in going always to the bottom, in order to find its food, requires a peculiar apparatus; and it is accordingly furnished with one. The subcutaneous muscle is remarkably strong; and it is voluntary over the whole body, in the same manner as it is over the human forehead, and in the skins of various animals, even pachydermatous ones; for the elephant can shake off not only an offending substance, but often a beast of prey, by this means alone. The power of the muscle in the musk rat is not directed to the shaking off of anything from it; for while it is in health the fur prevents all adhesion either of mud or water; but the muscle can expand and contract the whole skin, and thus alter the specific gravity of the body, so that it can ascend or descend in the water by mere changes of gravitation.

The naked part of the nose is the portion of its body of which this animal takes the greatest care; and it is said never to allow that to get dry—a state which would no doubt weaken its powers both of sensation and of motion. It is probable, too, that the continual agitation of this organ is intended to keep the muscles in constant readiness for those motions of which they are the organs, and without which the animal would be incapable of feeding, and would of necessity perish. There is an additional means of touch in this very complete organ. The circumference of the nostrils is beset round with short hairs, forming a sort of whiskers, which the animal has the power of projecting forwards or reflecting backwards at pleasure. When it is in a state of repose, they are always reflected; but when it goes to work they are advanced forwards; and as it can no more see the bottom in which it is to work, than it can see the small animals for which it searches there those appendages to the nose in all probability inform it of its arrival at a place fit for beginning its dabbling operations. Notwithstanding its blindness, it is not a nocturnal animal, but sleeps during the night, though it is said to keep up the motion of the nose, and even to change its place, during its sleep. Water is so indispensable to it, that Pallas was unable to keep one alive more than three days without access to it. When it is placed in a small quantity of water, that water is very speedily rendered most offensive to the smell; and when it is communicated to any substance, it remains for a great length of time. When Pallas was making his experiments upon the animal, he applied a thermometer for the purpose of ascertaining its heat which he found to be ninety-eight degrees of Fahrenheit, or nearly that of the human body. The thermometer got impregnated with the offensive odour of the animal, however, and retained it for fourteen years.

We may further mention of this very singular animal, and it is unquestionably the most singular subject of European zoology, and apparently peculiar to Europe, that the nerves which supply the organs of touch and of smelling are remarkably large, and ramified toward the naked part of the nose in a very thickly-netted plexus. The clavicles and the blade-bones are well developed, and bear about the same proportion as those of the mole, having to support both the digging and the swimming motions. There is but little action of the spine, and the habits of the animal do not require much. Of the dorsal vertebræ only the three last ones of thirteen have spinous processes. There are six lumbar vertebræ, five sacral, and twenty-six in the tail. We omitted to mention, in speaking of that instrument, that it is covered with small scales alternately with short scattered hairs. There are also some scales on the naked portion of the upper sides of the toes. Altogether it is a most extraordinary creature, both in its structure and its habits. There is no parallel to it in the whole range of the mammalia, and there is certainly no country possessing the same physical character as that part of Russia in which it is found. That country has a winter almost Siberian, alternating with a summer nearly tropical, and the changes from the one to the other take place without the intervention of any season deserving the name of spring or of autumn. As the name "musk rat" is calculated to mislead, by inducing the ignorant to refer the animal to a wrong order, it would be very desirable to change it.

for another popular one. The French call it the *Desman*, which is, we believe, the Swedish name, and there could be no objection to the adopting of the same in this country. The Russian would no doubt be the more appropriate name, but, like many other Russian names, it is a "jaw-breaker"—it runs thus, as nearly as our alphabet will bring out the expression of it—*Wuytcholschol*.

Pyrenean Species (M. Pyrenaica). This species is only half the size of the former, and differs much in the structure of the tail, almost sufficiently so in this, and some other respects, to entitle it to rank as a separate genus, or, at all events, to a separate subgenus. The tail is not compressed at the base, nor enlarged at a little distance from it. It is cylindrical, or nearly so, for the greater part of its length, and laterally compressed for only about the last fourth. It is also longer than the body of the animal, and its covering is different. It has no scales, but only a peculiar sort of flat hairs, which, however, adhere to the skin for the greater part of their length. The muzzle is much more produced than in the Russian species, indicating, perhaps, a habit of finding its food in more stubborn mould. The structure of its feet are much less aquatic, the toes of the fore foot not being webbed to the extremities, and the inner toes and the hind ones being entirely free. The covering of the body is the same in its texture as that of the other, but it is very different in its colouring. The upper part is a fine maroon brown, passing into greyish-brown on the flanks, and again into silvery on the belly; the whole of the face is dark coloured, instead of having a white space surrounding the eyes, and the lower side of the under jaw white, as in the other; in the arrangement of the teeth, those of the upper jaw very closely resemble the teeth of the mole; the bristly hairs around the muzzle are almost entirely rudimentary. This species has not been long known, and was discovered by M. Dessouais, Professor of Natural History at the Central School of Tarbes, on the French side of the Pyrennees. It was not found in the mountains or in the plain at the base where the current of the water becomes more moderate, and in this it, in so far at least, agrees with the Russian, or more typical species, which is found only on the margins of slow running or stagnant waters. It should seem that this small species is rare, for it has not been met with at the foot of any of the other mountains of southern Europe, and, even in the place where found, it has been but rarely seen. It does not appear to be an animal of nearly so interesting a character as the Russian; but still it is not a little curious that two animals, apparently peculiar to Europe, and differing so much from all the other European mammalia, should be found in regions so widely apart from each other, without any corresponding animal, or any approach to one, in the wide regions which intervene between their localities. There is not a great deal in the physical geography of the country at the foot of the Pyrennees which could assimilate that country to central or southern Russia; and yet there is a violent contrast in the seasons of the one locality as well as in those of the other. The narrowness of the country there, the difference of temperature in the two seas, the height of the mountains, and their continuation from sea to sea, and the consequent play of the atmosphere between the Mediterranean and the Bay of Biscay, certainly make the French side of the Pyrennees a peculiar

country; but still there is not much resemblance between it and Russia.

MYGALE (Walckenaer). A genus of spiders comprising the most gigantic species of the tribe, distinguished by having the palpi inserted at the superior extremity of the maxillæ, so that the former organs appear six-jointed, the first joint being narrow and long, with the internal angle at the tip porrected so as to perform the office of the maxillæ. The labium is small and subquadrate; the last joint of the palpi in the males is short, and in form of a button. The two anterior tibiæ have also, in this sex, a strong spur at the inferior extremity.

Latreille, who has paid much attention to this group of spiders, and published a valuable memoir upon them, in the *Nouvelles Annales du Muséum*, has divided them into two divisions or subgenera, both of which from the interesting particulars connected with them, it will be proper to notice.

In the first, or *mygale*, the tips of the chelicerae are not furnished with a series of moveable spines, and the hairs which clothe the underside of the tarsi form a thick and broad cushion extending beyond and concealing the ungues. Here belong the largest species of the family, some of which, in a state of repose, occupy a circular space of six or seven inches in diameter. The type of this genus is the *Aranca avicularia*, Linnæus, respecting the habits of which great incorrectness appears to have prevailed amongst naturalists. We are indebted to Mr. MacLeay for a correction of these errors; the following is an abstract of the communication of this gentleman, published in the first volume of the *Transactions of the Zoological Society of London*. The story of a spider which catches and devours birds appears to have had its origin with Madame Merian, in her splendid work upon the insects of Surinam. Oviedo, Labat, and Rochefort make no mention of any spider as possessing such habits; the two latter writers going no further than the statement, that in the Bermudas there exists one which makes nets of so strong a construction as to entangle small birds. Madame Merian, however, went the length of asserting that one spider not only caught but devoured small birds, and figured the *Mygale avicularia* in the act of preying upon a humming bird. Now, the *Mygale* does not spin a net [Madame Merian does not assert that it does so], but resides in holes under ground, and in all its movements keeps close to the earth, while humming birds never perch except on branches. The food of *Mygale* consists of *Juli*, *Porcelliones*, *subterraneau*, *Achete*, and *Blattæ*. A living humming bird and a small anolis placed in one of its tubes, were not only not eaten by the spider, but the latter quitted its hole, and left it in the possession of the intruders. The largest spider of the West Indies that spins a geometrical web is the *Nephila clavipes* (Leach,) and its net may probably, occasionally, be strong enough to arrest the smaller humming birds, but it is not likely that the spider would eat the birds. A small species of lizard, introduced into one of these webs, was enveloped in the usual manner by the spider, but, as soon as the operation was completed, the spider lost no time in cutting the line, and allowing her prisoner to fall to the ground. Mr. MacLeay consequently disbelieves the existence of any *bird-catching* spider.

The nest of this species is in the form of a tube, narrowed to a point behind, and composed of a whitish

web of very fine texture resembling muslin. The cocoon of the same insect, or rather the egg-case, is of the size and shape of a large nut, the outer envelope being composed of silk of the same kind as its nest, arranged in three layers. It appears that the young are disclosed within this case, and there undergo their first moulting. M. Goudot stated to Latreille that he had extracted as many as a hundred young from one of these cases. There are several species of these insects in Brazil, East India, and the Cape of Good Hope; and M. Dufour has also found one even in the arid deserts of Mozenta, in Spain.

In the second division of the genus *Cteniza*, (Latreille), the *Cheleceræ* are furnished at the tip with a series of moveable spines, and the tarsi are less strongly cushioned, so that the claws are not hidden.

The type of this division is the *Mygale cœmentaria* (Latreille; *Araignée maçonne* of Sauvages), or the mason or trap-door spider, so named on account of the curious structure of its nest, as observed by Sauvages, Dufour, and more recently by Audouin, who has published an interesting account in the "Annales" of the French Entomological Society. These spiders dig in the dry and mountainous districts of the south of Europe subterraneous galleries, of a cylindrical tortuous form, to the depth of many inches (sometimes two feet); they also construct at the mouth of the burrow, formed of silk and earth, a moveable operculum, or trap-door, which is so attached as to exactly fit the entry to the habitation, and to lift up and down.

These habitations are formed on an argillaceous kind of red earth; the walls are not left just as they are bored, but are first covered with a kind of mortar, which is subsequently coated with finer mortar, as smooth and regular as though a trowel had been passed over it. This coat is very thin and soft to the touch; within this is a tapestry of silk, having the lustre of satin, and almost always of a dazzling whiteness. These coatings render the nest impervious to wet. But the trap-door is the most singular part of the construction, being composed of more than thirty layers of earth and web, emboxed as it were in each other, like a set of weights for small scales, these layers of web terminating in the hinge, so that the greater the volume of the door, the more powerful is the hinge; and by another peculiarity in the construction of this nest, the strength of the hinge, and the thickness of the frame, are always proportioned to the weight of the door. Whenever, therefore, the spider enters her nest, or goes out, the door shuts of itself. Resistance is, however, experienced in endeavouring to open the door from without, and which M. Audouin supposes is caused by the spider within pulling down the door with her claws. Indeed, the inside of the door is remarkable for a semicircle of minute orifices, placed on the side opposed to the hinge, about thirty in number, the object of which M. Audouin considers is to enable the animal to hold the door down, in case of emergency, against external force, by the insertion of its claws into some of them, the claws, as above stated, being furnished at the tip with a series of moveable spines. There are several of these trap-door spiders, one of which is found in the Island of Naxos (*C. ariana*); another in Jamaica (*C. nidulana*); a third at Montpellier (*C. cœmentaria*); a fourth (*C. Sauvagesi*, described by M. Audouin) in Corsica; and a fifth found in various parts of New South Wales, by Mr. Bennet, and described in his

Wanderings in that Island (vol. i. p. 328). Mr. Kirby has figured the Jamaica species and its nest in the frontispiece to the second volume of his Bridgewater Treatise, in which he has also copied M. Audouin's figures. M. Dufour is of opinion that it is the females alone which construct these nests, the males being generally found under stones, and their structure not appearing so well adapted for building as those of the females.

MYGALURUS (Lamarck). A genus of European grasses, chiefly annuals, and therefore not in cultivation. In English botany they are called *Festuca*, or mouse-tail.

MYGINDA (Jacquin). A genus of bothouse shrubs (except one, the *M. myrtifolia*) belonging to *Rhamnææ*. The plants delight in a loamy soil, and are increased by cuttings.

MYLABRIS (Fabricius). A genus of coleopterous insects, belonging to the family *Cantharidæ*, having the antennæ eleven-jointed in both sexes, thickened towards the tips, with the last joint distinct and larger than the preceding; the body is long and sub-cylindric, and the thorax narrow. This is an extensive genus, consisting of handsomely marked species, none of which are inhabitants of this country, although some inhabit the more southern parts of Europe. The type is the *Melœ chircori*, Linnæus. Several species are employed as vesicants, having powers similar to those of the blister-fly, *Cantharis vesicatoria*.

MYLOCARYUM (Willdenow) is the buck-wheat tree of Georgia, belonging to *Ericææ*, formerly called *Cliftonia ligustrina*.

MYOCONCHA. A genus of molluscs, established by Sowerby in his Manual of Conchology.

MYOPOTAMUS—The Coypou. A genus of rodent mammalia, resembling the beaver in size, in the places of its habitation, and in some other particulars, but differing from it in geographical distribution, and in other respects, being found only in the tropical parts of America, whereas the beaver is found only in the cold regions of the north. This animal is very generally distributed over the warm parts of South America, where it is found on the banks of the streams, and chiefly, indeed, inhabiting the waters where it finds the principal part of its food. The first correct notice which we have of it is in Molina's account of Chili, coypou being its name in that country. It is also mentioned by D'Azzara, in his natural history of Paraguay, under the name of *Quinya*; and it was also observed by Commerson, (after whose death an account of it was found among his papers,) as the type of a new genus, under the name myopotamus. Commerson left a drawing of the animal; and between that and the account given by the natural historian of Paraguay, the characters and relations of this addition to the rodentia of South America were tolerably well made out. Long previous to this, the skin had been by no means an unimportant article of commerce; but it was not until five or six years of the present century had elapsed that the animal itself was known, even to the naturalists of Europe. For a long time the researches of those naturalists were confined to the ransacking of the warehouses of furriers for the purpose of examining the skins; but as no attention is paid in the procuring of such skins, to preserve the characters of the animals to which they belong, the results of those examinations were far from valuable; and a long time elapsed before anything else than the mere external were

known even to the most learned in zoology. The name *myopotamus*, given to the animal by Commerson, is nearly synonymous with *hydromys*, the common name of almost all aquatic rodentia except the beavers; and it was understood to have no inconsiderable resemblance to two Australian species lately discovered in its external characters generally, and especially in the structure of the feet, which are all five-toed, the fore ones with the toes free, and the hind ones with them webbed. In consequence of this it was considered as belonging to the genus *hydromys* as then established; but when its system of dentition came to be examined, it was found to resemble much more the dentition of the beavers, having four cheek teeth in each side of both jaws, as the beavers have, and not two, as in the genus *hydromys*, though the number of incisive teeth in both are the same, namely, two in each jaw. This different structure of the mouth indicated a different species of food, more difficult of mastication, and approaching to that on which the beaver subsists; and after this discovery had been made, it was found, upon further examination, that there were great and very characteristic differences between it and those animals of New Holland with which it had at the first been classed. Its body is much less vermiform, that is, slender and flexible, and capable of twining its way among bushes, than the bodies of these. Its claws, also, are much larger, blunter, and not nearly so much arched; and its tail is less hairy than theirs, and more covered with scales. All those differences indicate not only an animal of very different habits, but an animal whose habits are decidedly more aquatic. The lithe bodies, the crooked claws, and the hairy tails of the Australian animals, afford proofs that they seek for some sort of prey, either animal or vegetable, among the tangled herbage on the margins of the streams, whereas the opposite characters of the same structures, in the South American animal, are equally conclusive evidence that the water is the grand theatre of its action. This being ascertained, it became necessary to establish this animal into a new genus, and Commerson's name has been retained, while the name given by Molina has been Latinised as the specific one. At present, however, there is not much need for a specific name, because there is no other known species of the genus, nor is it very probable that another will be found; but the specific name leaves the generic one open in case that such a discovery should be made at any future period.

This is in some respects a curious animal. The beaver, properly so called, is found only in cold countries; and so is the sub-genus *Fiber*, which agrees with the water-rats and field-mice in the structure of its teeth. This animal approaches more nearly to the beaver in dentition, which is the essential character of an animal, than any of the rodentia even of cold countries; and yet it is found only in the warm parts of America. It is therefore a sort of anomaly in the animal world; for it is not a little remarkable to find in the tropical and the polar parts of America two animals resembling each other so nearly in their teeth, and also in the covering of their bodies; while polar and tropical animals are not only in general very different in the coverings, but that the covering of an animal undergoes a decided change when that animal is transferred from the one of these localities to the other. It must be borne in mind, however, that both the coypou and the beaver spend

most of their time in the water; and that the difference of temperature of the water in different latitudes is very small, compared with that of the earth or the air. Besides, the streams of South America near the Andes (and it is in these, rather than the broad waters of the plains, that the coypou resides) contain a considerable portion of snow-water all the year round; and thus their temperature is low in proportion to the latitude. The existence of this animal in warm latitudes may be regarded as a proof of the influence which melting snows can exert upon the waters even of a tropical climate. There is, as we have said, only one species of this curious animal; and this species we shall now very shortly notice.

THE COYPOU (*Myopotamus coypus*.) This animal is among the largest of the rodentia, measuring about one foot nine inches and a half in length, independently of the tail, which is about one foot two inches and a quarter. The legs are rather short, as compared with the size of the animal, being not above four inches and a half in length. The incisive teeth are maroon red on their external surfaces; the claws are black; and the ears, which are small and rounded like those of the genus *Hydromys*, have the convex surfaces thickly covered with short hair. The general colour of the fur on the back is maroon brown, becoming brighter on the flanks, and passing into bright red; while the tint of the belly is reddish sand-colour. These colours are liable to apparent changes, however, being of a different tint when the animal bristles them up, than when they are laid flat. Each hair is brownish ash at the root, and bright red at the point. The felt, or fine fur which is concealed under the long hairs, is brownish ash, rather deep in the tint on the upper part, but paler on the belly. As is the case in all aquatic mammalia, the hairs on the tail are few, short, and stiff; they are of a reddish sand-colour, and interspersed with scales on the naked parts. The circumference of the mouth, the termination of the muzzle, and the mustachios, which are long and stiff, are white, but the mustachios are interspersed with some black hairs. These animals are, however, affected with albinism in a good many instances; and it is worthy of remark that this affection is so common in some parts of tropical America, that it is not rare among the people of colour. The albinos of the coypou are not, however, entirely white; for in them the maroon on the back is changed to red and the red on the flanks to a very pale tint of the same. It is possible, however, that these supposed albino skins may be merely those of young animals or of females; although D'Azzara says that the female is very like the male.

The skins of these animals have for a long time been imported into Europe in very great numbers; and the soft under-fur has been employed in the manufacture of hats, in exactly the same manner as the under-fur of the beaver.

The manners of this animal are imperfectly known, nor have its geographical limits been settled with that precision which would be desirable. D'Azzara and Molina are still the authors who have published the best and almost the only accounts of this animal, though, from the researches now going on, we may anticipate that before long we shall be better acquainted with this, and with all the other peculiar animals of South America, whose history, could we obtain it fully and satisfactorily from actual observation, would be one of the most interesting chapters

U

in the book of living nature. The authors alluded to describe the coypou as inhabiting the banks of the rivers, where it digs a burrow with its claws; and it must be admitted that, from their structure, they are well adapted for such a purpose. It is said to be an excellent swimmer, very gentle and inoffensive in its manners, and by no means difficult to tame. In a domesticated state it is also very accommodating in respect of food, eating almost anything that is given to it; and it shows much gratitude and affection to those who are attentive to it and supply its wants. It is rather a fertile animal, the female producing as many as six or seven at a litter; but then its skin is in such request as an article of commerce, that it is sought for and destroyed with nearly the same avidity as the beaver is in North America. It is not a little remarkable that an animal resembling the beaver so much as this does in the system of its teeth, should yet be so very different in the economy of its habitation. The beaver never burrows, even, we believe, in the case of those solitary individuals which, for causes unknown to us, are expelled from the regular communities; and, excepting in the case of those expulsions (and they form the exception, not the rule), the beaver is a social animal. The coypou, on the other hand, burrows, but never builds, though it probably carries leaves and grass into its burrow in the breeding season, as is done by almost all animals which frequent the banks of rivers, or otherwise form their habitations in humid ground. The difference of character in the places which they inhabit may be one cause of the difference in manners between this animal and the beaver. The streams of the northern parts of North America, upon the banks of which the beaver is most abundant, are subject to be flooded for a considerable time during the spring freshes; and thus a burrow so constructed as to allow the animal an outlet under water, and a dwelling in the air at the same time, could not be formed but at an expense of more labour than the beaver requires to exercise in the building of its hut. Where the coypou inhabits, floodings are by no means so common, and when they do occur, they are of very short duration. They do not occur in tropical South America, and hardly, indeed, nearer the equator than the thirtieth degree of south latitude; and, though the countries there have their rainy seasons, drought is the prevailing character. Chili, Tucuman, and part of Buenos Ayres, are the places where chiefly this curious animal is found; and they are countries very unlike in their physical geography to the beaver's country in North America. Still it is not uninteresting to find that though the northern part of the American continent is subject to greater vicissitudes of seasons, and more severity of cold in the winter, than any other part of the world, while in the south the seasons are comparatively uniform, and a tropical character is preserved up even to the Strait of Magalhaen; yet that both are fur countries, and fur countries to a very considerable extent. It is true that the furs of the south are not so numerous, and perhaps not so valuable, as the better ones of the north; but a country which furnishes the chinchilla from its dry hills, and the coypou from the banks of its streams near the mountains, must always be regarded as an important fur country. As is the case with the whole of South America, we want information with regard to the peculiar localities of the coypou.

MYOPORINÆ. A small natural order of plants, comprising four genera and eighteen species, already

described. They are mostly natives of New Holland and the South Sea Islands. The leaves are simple, alternate, or opposite, with no stipulæ. The flowers are scarlet, white, or blue coloured, axillary, and without bractæ. This order contains *Myoporum*, *Bontia*, *Avicennia*, and *Stenochilus*: the last being the handsomest of the order. The *Avicennias* are shore plants like the mangroves, shooting their long roots to a great distance among the mud, or on the surface, five or six feet before they turn downwards to fix themselves. All the species may be kept in the stove or greenhouse, and only require ordinary treatment.

MYRIAPODA—hundred legs (Latreille). Under this name Latreille united together the two orders *Chilognatha* and *Chilopoda* of Leach, which it is true possess many characters in common, as stated in the article upon the former of these two orders, but which have been considered as being respectively of equal rank with the orders of winged insects by our English authors, whose classification we have in this respect adopted.

MYRICA (Linnaeus). A genus of deciduous and evergreen shrubs found in different parts of the globe, one of which, the *M. gale*, is the sweet gale of Britain, and the *M. cerifera* is the candle-berry myrtle of North America. The flowers are diœcious, and the genus belongs to *Amentaceæ*. The root of *M. cerifera* is a powerful astringent, but it is more prized for the wax it bears than as a medicine; and in some parts of North America, where animal tallow is scarce, its annual crop of wax is collected and made into candles. Our common gale yields wax, but much less abundantly.

MYRIPRISTES. A genus of spinous finned fishes, belonging to the perch family, having the abdominal fins under the pectorals. They are covered with beautiful scales, and have two rows of toothed scales on the gill-lid, but no spine at its angle. One of their most remarkable characters is the form and situation of the air-vessel, which is divided into two lobes anteriorly, and attached to the bones of the cranium in such a manner as to separate entirely the cavity which contains those hard substances which are understood to be the principal organs of hearing in fishes. The intimate connexion between the air-vessel and these organs in this genus of fishes is a singular point in natural history; but it is one the physiology of which is involved in great obscurity. There is a curious connexion between the characters of different latitudes, and those of the fishes most abundant in these latitudes, which cannot be explained,—either by the slight difference of temperature of the sea, or by the different action of the solar beams considered merely as light and heat. The tropical fishes are remarkable above all others for their brilliancy, and for the superior development of those organs which we suppose contribute to the sense of hearing; and it should seem that fishes are far more sensible to, and far more influenced by, the different electric states of the regions which they inhabit, than we would at first suppose. There is also an obvious connexion between the air-bladder in fishes and their susceptibility to electric influence; though what it is, or how it operates, we are unable to tell. There is no question, however, but that, in the case of tropical fishes, which inhabit where the sea is often subject to violent thunder-storms, there is a sort of presentiment, or affection of their systems, by means of which they anticipate the storm and avoid its violence.

We find in our own rivers that brilliant lightning and loud thunder invariably send down the fish; so that, although there is often good fishing in a shower, there is seldom, if ever, good fishing in a thunder shower. Now, if we find this in our latitudes, where the electric action of the atmosphere is so mild and limited, we may be prepared for finding it to a much greater extent in those tropical climates where this action is at a maximum. To what depth the sea may be so much electrified, even in the most violent thunder storms, as to benumb the muscular irritability of fishes, we are unable to say; but there is no doubt that they are possessed of means which give them warning of the approach of such storms, and that they avoid them. The fishes of the present genus are found in the tropical seas of both hemispheres, but not in cold or temperate latitudes. Nothing whatever is known of their manners.

MYRISTICA (Linnaeus). A genus of three species of tropical trees and shrubs, one of which is the cultivated *M. moschata*, the true nutmeg, being the type of the order *Myristiceæ*. Generic character:—flowers dioecious; calyx three-toothed; stamens forming a thick column; anthers linear, two-celled, united; style short, pyramidal; stigma of two lobes; drupe one-seeded, nut covered with an arillus; arillus fleshy; albumen firm, veined, and marbled. Of the several species of *Myristica*, the common nutmeg is the most valuable and best known; aromatic fruits are, however, borne by others, such as the *M. otoba*, which is the nutmeg of Santa Fé, and *M. Horsfieldia*, which is a native of Ceylon, where there are several other varieties. The fruit of *M. tomentosa* is often fraudulently mixed with ordinary nutmegs, but it is an inferior spice.

The English residents at Bencoolen, and other settlements in that part of the east, cultivate the nutmeg with success; but they do not seem to thrive in the West Indies. The nutmeg or seed, with its arillus or mace, are powerful carminatives, and in large doses are dangerous, but in proper doses are cordial medicines. The natural order to which this genus gives a title is—

MYRISTICEÆ, which contains only one other genus, viz., *Hernandia*, of both of which there are only six species as yet described, three of each genus. The *Hernandias* are large Indian trees, called by the English Jack in a box, from their fruit being sonorous when shaken. Nutmeg plants are as yet scarce in our collections, but the *Hernandias* are common and easily propagated.

MYRMELIONIDÆ (Leach). A family of neuropterous insects, having the tarsi five-jointed, the body long and slender, the head not produced into a rostrum, the antennæ thickened at the tips, the wings of equal size, and in repose applied against each other above the back, like the roof of a house; the ocelli wanting, and the legs short. These insects are found in warm situations in the meridional coun-

tries of the Old and New World; they fly but little during the day, remaining quiet amongst the leaves of different plants. The habits of the larvæ are, however, quite the reverse of this. In this state the insect is known under the name of the ant-lion (*Myrmelion*

formicæ, Linnaeus), which it has obtained from the great havoc which it makes in destroying ants and other small insects in an exceedingly ingenious manner. The abdomen is very large, in proportion to the rest of the body, and fleshy; the head small, flattened, armed with two long jaws like horns, or rather more like a pair of calliper compasses, but serving as instruments of suction instead of mastication, being channelled on the under side. These organs have indeed been described as perforated and tubular, but such is not the case; the maxillæ, which have been overlooked or considered as a portion of the mandibles, fitting into the channel, and assisting in suction; the body is grey or sand-coloured; although provided with legs, these organs are so unfitted for active motion that the insect is unable to follow its prey, like the larvæ of the *Hemerobiidæ*, which in several respects it very much resembles; indeed its ordinary motions are either backwards or sideways. How then is this slow unwieldy animal to obtain a supply of food, consisting as it does of insects of such activity as the ants? This is effected by means of a snare or pitfall, which it excavates in the sand, at the foot of which, when completed, it takes its station; but, lest its hideous form should alarm its victims, it buries itself at the bottom, leaving only the head exposed.

Pitfall of the Ant-lion.

These pitfalls vary in diameter from one to three inches, according to the size of the larva by which they are constructed. When the insect has fixed upon a spot for its retreat, it first marks out a circle, to which the exterior of its intended pit is to extend: it proceeds working backwards, shovelling or scooping the sand by means of the fore leg on the side which is nearest the centre of the hole, upon the back of its head, and which it then, by a sudden jerk, throws several inches beyond the circle; in this manner it proceeds circle after circle, but alternately reversing its position, so that the opposite leg may alternately be employed as a shovel; and so quickly does it carry on its operations, that in the course of half an hour it has raised a cone of sand equal in diameter to the diameter of its pit. Sometimes, however, it meets with serious obstacles—pieces of stone, &c., interrupt its path, and which require the greatest exertions to remove; sometimes it is able to effect this, which is done by jerking the stone with its jaws beyond its burrow; but, in case the stone is much heavier than itself, it contrives to place the stone upon its back by the alternate motion of the rings of the body, and in this way carries it up to the margin of its cell, when it rolls it away. Sometimes indeed it is unable to perform this, and, after various ineffectual attempts, is compelled to quit the spot and recommence the form-

ing of a fresh pit in another place. When it has completed its work it has now to lead a life of wearisome patience. It takes its station at the foot of the pit, and there waits until an unlucky chance brings some hapless ant down the precipice, which it immediately seizes with its exerted jaws, sucks, and then casts away with a jerk. If the unfortunate insect should happen to struggle, and endeavour to escape, it showers upon it, by means of a jerk with its head, a quantity of sand, which seldom fails in bringing it within its reach. The nutritive matter which it extracts from its prey is not converted into excrement; this insect, as well as various others, having no anal aperture. From its habits it may be imagined that it is enabled to undergo a long-continued fasting. When it is full grown it forms for itself a perfectly round cocoon, of a white shining silky matter, externally covered with sand, within which it is transformed into a short curved inactive pupa. In about fifteen or twenty days the imago bursts forth, in a form quite unlike that in which it had previously appeared, leaving the exuvie of the pupa sticking in the aperture formed for its exit out of the cocoon. There are many species of this genus, some of very considerable size, being larger than the largest dragon-flies. In all the species the wings are most beautifully reticulated, resembling the finest lace-work, and variegated with dark spots and markings, giving the insect a very elegant appearance.

The other genus belonging to this family is *Ascalaphus* (Fabricius), the species of which constitute one of those interesting groups of animals, which, whilst possessing the real character of one tribe, assume the appearance of another totally distinct, exhibiting what has been termed a relation of analogy in distinction from one of affinity. This kind of relationship is met with in almost every group of animals in a greater or less degree; and from the frequency of its occurrence naturalists are led to believe that in the great and natural distribution of animated nature—that system, in fact, which places every animal in its own situation with reference to the habits and structures of every other animal—these analogies are not casual circumstances, but necessarily attend the higher and more close relations of affinity. If we examine then the essential structure of *Ascalaphus*, we shall find that in its oral apparatus, the structure of its wings, legs, &c., a very close affinity exists between it and the ant-lion flies (*Myrmeleon*). They are therefore placed in the same family, this being an instance of the closest connexion which can exist between two genera. But if a person unused to the examination were to be shown an *Ascalaphus*, he would immediately call it, as some authors have even done, a butterfly—the antennæ between long, slender, and clubbed at the tips, and the wings of moderate size, and ornamented with various colours, although not clothed with scales; this, therefore, is an instance of analogy, or the most distant relationship which can subsist between two genera. The species are chiefly found in the south of Europe. They inhabit hot sandy districts, and fly quickly.

MYROBALAN PLUM is the *Prunus myrobalana* of Linnaeus, a fruit tree, of which the fruit is but very inferior in quality.

MYRRHIS (Morison). A common British plant well known as myrrh, esteemed for its pleasant scent, belonging to *Umbellifera*. It has been long in cultivation, and formerly was much more used than at

present. Its leaves were used in salads, and its roots were eaten either boiled or made into tarts or sauces, or candied as a sweetmeat. In the North of England the seeds are employed to perfume and polish oaken floors and furniture.

MYRSINÆÆ. A natural order, comprising eight genera, and above fifty-two species, all greenhouse and hothouse plants. The plants of this order are nearly allied to *Primulacææ*, only the former are arborescent, while the latter are herbaceous. The genera here associated are *Mæsa*, *Jacquinia*, *Ardisia*, *Corynocarpus*, *Embelia*, *Myrsine Mangliilla*, and *Clavija*. Some of the *Ardisias* are very beautiful; the *Jacquinias* are also highly ornamental, and all of them thrive under the ordinary hothouse management.

MYRTACEÆ. A most important natural order, as well for the number of genera it contains as for the beauty of their flowers and usefulness of many of their fruits. Thirty-seven genera, and nearly three hundred species, are already in our books. The myrtles and their typical allies are trees or shrubs, with often angled branches and simple exstipulate leaves, mostly opposite, but rarely alternate or in whorls, as in some of the *Melaleucææ*. The substance of the leaves is mostly coriaceous, and furnished with numerous dot-like receptacles, containing aromatic essential oils, on which their fragrance depends. The inflorescence is both terminal and axillary, variable in its form, generally aggregate, the blossoms being seldom solitary. The flowers are united and regular, white or red, occasionally yellow, but never blue. The tube of the calyx is adherent to the germen; the limb four to six-cleft, persisting or deciduous. The petals (rarely wanting) are equal in number to the lobes of the calyx, and alternate with them. The stamens are seated round the germen, and are, when not indefinite, two or three times the number of the petals, and often arranged in several series; the filaments are distinct or connate; the anthers are small, oval, two-celled, and open lengthways; the germen is inferior, and one to six-celled; the style is single; and the stigma in general is simple and entire; the fruit is various, either dry or fleshy, sometimes capsular, or baccate, or drupaceous, and many or one-seeded.

MYRTLE is the *Myrtus communis* of Linnaeus. Of this favourite plant there are ten garden varieties, differing chiefly in the form of their leaves and manner of growth. There are thirteen other species, mostly natives of warm countries. They are all easy of cultivation.

MYSIS—the opossum shrimp (Latreille). A curious genus of podophthalmous crustacea, forming the type of the order or sub-order *Schizopoda*, so named from the legs being cleft near the base, each composed, as it were, of a pair of legs. The three external pairs of maxillæ, or foot-jaws, which in the shrimps serve for manducation, are here transformed into legs; so that, instead of five pairs of these organs, there are eight; and as each leg is doubled, or bifid, these shrimps may be said to have thirty-two legs. Another peculiarity is, that the females are provided with a pouch on the under side of the body, in which they carry their young for a considerable period after they are hatched. The shell is slender, and none of the legs are cheliferous; the tail is terminated by a swimming apparatus. The type of this genus is the *Mysis Fabricii* (Leach), or the *Cancer oculatus* of Otho Fabricius. Mr. J. V.

Thompson has published a very valuable Memoir upon this genus in his Zoological Researches.

MYTILACEA. De Blainville's fourth family of the third order *Lamellibranchiata*: it includes the genera *Mytilus* and *Pinna*, third class, *Acephalophora*.

MYTILUS. (Lamarck, Linnæus.) The genus *Mytilus*, now consists of such examples of the Linnæan *Mytili* as are regular, equivalve, and longitudinal molluscs, of a solid and not a lamellar structure (as in the oyster): they have pointed apices at the inferior end, nearly straight or slightly curved, and attached to other substances by a byssus of a short thick texture; the cordinal ligament is lateral, and a considerable portion of it internal; by which, as well as the different position of the apices, it is easily distinguished from its congeners. The *Mytilus edules*, or common muscle, is so well known that a more detailed description is needless; it furnishes an abundant and nutritious article of food, in some countries forming nearly the only dependence of the inhabitants, as an article of common food. The immense consumption of this mollusc, in the London markets alone, exceeds all calculation notwithstanding the prejudice existing against them as sometimes possessing a poisonous quality. It is not, however, the only shell-fish which produces bad effects on certain persons; and it is probably occasioned by a peculiar state of disease in the animal. Every known part of the world produces what are familiarly termed muscles, and their abundant distribution indicates their goodness as food for man, since Supreme Wisdom has ordained that everything noxious to life is far less productive than those creatures which are not injurious, and intended to be eaten.

MYXINE—Hag. A genus of *Chondropterygians*, or cartilaginous fishes, with fixed gills; and standing as it were on the very verge of the vertebrated animals, and forming a sort of link between them and the mollusca. For this reason, though the fishes themselves are of uninteresting appearance and small size, and perfectly useless in an economical point of view, they are highly interesting to the student of nature. They belong to the family of suckers, or *cyclostoma*, following in order the lampreys and the sand-eels, to which they have several points of resemblance. They are, however, so nearly destitute of anything which can be called a skeleton, so destitute of eyes, of jaws, and all the other characteristics of more typical vertebrata, that naturalists were for a long time puzzled where to place them in the system. This puzzle was further increased by the situations in which these fishes are usually found, which is generally in the interior of cod and other voracious fishes, upon which they fasten with their sucking mouth, and consume the substance with no ordinary degree of rapidity. The fact of their being found there, with the uncertainty of their mode of increase, led several naturalists, and among others the justly-celebrated Linnæus, to conclude that they are *Entozoa*, or, as he called them, "intestinal worms." This is not the only mistake which has been committed relating to *entozoa* and fishes; for there is a tolerably large and very peculiarly-shaped parasite, which breeds in the intestines of eels, burying its head between the coats, and extending its body along the canal. Now this species of *entozoa* was long considered as the young of the eel; and, for no other reason than that it is subject to "worms in the belly," the eel was set down as a viviparous animal, or one which brought forth its

young alive; nor was it till after Mr. Yarrell had exhibited one sex of the eel with melt and another with roe, again the roe ready for spawning, and yet again the "shotten" eel, flaccid from the newly-discharged spawn, that "the learned" gave up this most singular prejudice. Singular indeed it was, and at violence with every known law of physiology; for though there are recorded instances of extra-uterine gestation, there is no instance whatever of the young of any animal coming to maturity, or at all existing in the intestinal canal. That canal is the avenue of death to every living thing that enters it, or if it is not death to the enterer, it is certainly death to the animal entered. This fact is universal, and applicable to the whole of animated nature; so that, whenever any hypothesis is contrary to it, we require no argument and no investigation to convince us that that hypothesis is utterly without foundation.

The myxine is an animal certainly well calculated to perplex systematists, as it combines some of the characters of the fish with some of those of the *cephalopoda*, or order of mollusca, which, in their general structure, make the nearest approach to the vertebrated animals of any that are to be found among the invertebrated ones. The external appearance indeed resembles a worm more than anything else; but even here the possession of a fin would determine it to be a fish, although there were no more decided characters founded upon its internal structure. Perhaps we shall place this curious subject more clearly before our readers by quoting, from Mr. Yarrell's "History of British Fishes," his very clear and satisfactory description of this singular animal. "The body," says Mr. Yarrell, "is elongated, eel-like in form, cylindrical throughout the greater part of its length, tapering and compressed towards the tail; the whole length from twelve to fifteen inches; the skin perfectly smooth and unctuous; the head obtusely pointed; with a single spiracle connected with the mouth and branchiæ; eyes wanting; eight tentacula, cirri, or feelers, as they are called, are placed about the lips, four near the front, and two on each side; lips soft, extensible, inclining to a circle in their figure; one single-hooked tooth on the palate; the tongue furnished with four rows of small pointed teeth, two rows on each side; at the division between the thoracic and abdominal cavities are two external apertures, each of which is connected by a membranous tube with the six branchiæ of its own side; hence Bloch's name of *Gastrobranchus*. The anal aperture is an elongated fissure, situated about two inches before the end of the tail; along the whole surface of the body are ranged two rows of pores, which afford egress to the secretion of the numerous glands within; the dorsal fin is low and rudimentary, except towards the tail, where the membrane is dilated, and being continued round the end of the tail, and thence upwards to the anal aperture, forms, in addition, a caudal and anal fin, which no doubt materially assist the fish in swimming. In colour the myxine is dark brown along the back, lighter chestnut brown on the sides, and yellowish white underneath."

There are two species of this singular genus of fishes, or perhaps, rather, we ought to say that there are two genera or sub-genera, and that these extraordinary creatures form a group in nature. The most accurate systematists distinguish them by the number of breathing apertures in the sides; and, of the two which are known, one has seven such openings.

on each side, and the other only one. For this reason the first has been called *Heptabramatus*, and the second *Gastrobranchus*; thereby implying simply that the first has seven openings to the breathing apparatus on each side, while the second has only one such opening, as if its gills were in its belly. It should seem that those differences are quite sufficient for establishing a generic distinction between the two animals; at least, genera are founded upon slighter differences in many parts of the system of animated nature; and Cuvier, who, notwithstanding the pretended refinements of later and far less experienced authorities, does make a distinction of this kind, although, as his object is to place nature itself before his readers, and not his mere opinion of it, he is by no means dogmatical on this point. Of the two species, or genera, or whatever else we may call it, one belongs to the northern hemisphere, and the other to the southern; and, so far as we have been able to ascertain, they do not meet each other in the middle latitudes; neither is there, so far as is known, any analogous fish to be met with there. The northern one, which is the most peculiar in its structure, is not, we believe, met with in the warmer seas even of Europe; and on the British shores it frequents the comparatively cold waters of the eastern sea, in preference to the warmer tide of the Atlantic. The one belonging to the southern hemisphere has not been so frequently seen, or seen in so high latitudes, as the northern one; but it has not been met with in any of the tropical seas of the southern hemisphere; and thus it is probable that it is also a fish of temperate and even of cold latitudes.

DOMBEYA'S MYXINE (*M. Dombeyi*). This species has no dorsal fin; but the anal and the caudal exist, and are united at the extremity. It is blunt at the posterior extremity; and the anterior one is enlarged into something resembling a head, though without the usual organisation of that part even in fishes. It has seven breathing apertures on each side of the body, the same as the lamprey has; but in the form of its mouth, and the perfectly rudimental state of its vertebral column, and, indeed, in its general characters, it more nearly resembles the myxine of the European seas. Hitherto it has been found only on the coast of Chili; but whether it exists on other coasts, in corresponding latitudes of the southern hemisphere, has not of course been ascertained. Besides its curiosity as a subject of natural history, it possesses no manner of interest; for in an economical point of view it is without value, and its services in the economy of nature cannot be very great.

THE HAG (*M. glutinosa*). This species gets the name of hag from getting into the interior of fishes, and consuming their substance; and the epithet *glutinosa* is added in consequence of the vast quantity of mucous or gelatinous matter which it secretes from the two rows of pores along the sides of the body. Almost every fish is provided with pores of this description; and the secretion seems to be necessary, both for preserving the flexibility of the skin, and for preventing the water from acting upon it. As the spinal column of this fish is little else than a flexible tube, its muscles have a less stable point of insertion than those of fishes in which the back bone is better developed; and consequently it has more need of the secretion for lubricating the skin, so as to allow the muscles to produce their proper effect. It is indeed a general, though not an absolutely uniform law, that

the secretion from the skin in fishes is inversely as the bones of their skeleton; for the cartilaginous fishes have more of it than the bony fishes, and among the latter the soft-finned fishes have more of it than the fishes which have spinous rays to their fins, and harder bones. The fact of this secretion being inversely as the development of the skeleton shows us, that, in proportion as the bones are more flexible, provision is made for greater flexibility in the skin; and, altogether, the fishes with the soft bones are more gelatinous, and, generally speaking, are less provided with regular scales, though many of them have spines, or plates of hard bone, upon the skin, and thus make a slight approach to those molluscan animals which are covered with scales. The hag, though one of the least bony of the whole race, has no hard substance produced by the skin; but that skin bears a considerable resemblance to the cloak of some of the cephalopod mollusca, supporting the muscles at least as much as the rudimental spine does, and therefore require to be lubricated by the glutinous secretion given out by the animal. The quantity of this given out is much greater than one would be disposed to believe. Kalen mentions that, having put one of these fishes into a large pitcher of sea-water, the quantity which it gave out was so great as, in a very short time, to convert the water into a transparent jelly or glue; and that, when he placed it in an additional quantity of sea-water, that also was very speedily reduced to the same state. The communicating of so much of this secretion to the water could not be for the purpose of lubricating the skin of the fish; and hence some have concluded that the myxine, which is totally blind, and appears to have no distinct organs of sense excepting the eight tentacula around the mouth, employs this discharge as a means either of offence or of defence, though which of the two is of course not known.

Considered as a British fish, the hag is not rare on the eastern coast, though little mention is made of it on the western. Pennant says, that it "enters the mouths of other fishes when on the hook, which remain a tide under water, and totally devours the whole except the skin and bones. The Scarborough fishermen often take it in the robbed fish on drawing up their lines." That it is found in the bodies of fish is certain, and it is equally certain that it goes there for no other purpose save that of feeding on the substance of the fish; but how it gets in is another matter, and one upon which the authorities are not exactly agreed. Some say the mouth, others say the very opposite end of the digestive organs; while others, again, allege that it makes an opening for itself, and for this reason it is, upon some parts of the coast, called the "borer." We do not venture to decide on this grave matter, though we are inclined to lean to the third opinion; because it is very uncommon, and also unlikely, that any animal should enter the intestinal canal of another, at either end, for the purpose of eating that other; and besides, the hag, with its two rows of teeth upon each side of the tongue, acting against each other something like a pair of lateral jaws, and its strong crooked tooth on the palate, is pretty well adapted for making an opening for itself. The mode in which it makes its attack is a mystery, however, and one which it may not be very easy to clear up. The attack is, however, not made singly; for Wilson mentions that, on the shores

of Norway, where this fish appears to be more abundant than on any part of the British shores, as many as six have been found in the skin of a single haddock, the flesh of which they had almost entirely consumed. On our coasts it is most generally found on the cod and haddock banks, and we believe more rarely in the deep-water fishings. It seems also to be more abundant the more northerly the situation, provided the bottom is adapted for those fishes upon which it appears chiefly to feed. The breathing apparatus is one of the most curious parts of its structure. There are twelve branchial cells, six arranged on each side, and these communicate singly with the internal canal; but the communications externally are with a common tube on each side, so that there are only two openings outward from the breathing apparatus. There is also only one inwards, or from without, more strictly speaking, namely, the spiracle mentioned in the quotation from Mr. Yarrell. How the breathing of the animal is carried on by means of this singular apparatus is not easily understood; but the probability is that it is very slow, and that the grand labour of the animal consists in the manufacture of that species of glue which it secretes in such abundance. Looking at the simple structure of this animal, its slender form and its soft texture, one would be led to conclude that it is one of the least offensive, and least capable of doing active injury, of any of the race. It is never found above fifteen inches in length, and rarely more than a foot; it is not thicker than the little finger; and it is not only blind, but absolutely without anything that can be positively called a head, or, at all events, a head furnished with jaw-bones, and the other parts which characterise the heads of vertebrated animals; but we should be in error were we to estimate what nature can accomplish by our notions of the means of its accomplishment; and thus the hag, which appears so imperfectly formed and so helpless, can "spoil the spoilers," and feast upon the most voracious fishes, in spite of any effort they may make to the contrary. The common supposition is, that the hag does not attack any fish until that fish is caught on a hook, or fixed by some means or other. But this is very unlikely. We know no means by which a living fish can be fixed in the water except on a fisherman's hook; and dead fishes very speedily float to the surface, and turn up to the air that side at which alone the hag is supposed to enter. To suppose, therefore, that the hag cannot feed except upon fishes which are fast, is supposing, in other words, that it cannot live without the art of man—a supposition which is contrary to every analogy of nature. As found parasitical in the bodies of fish, (and this is the way in which it is usually found), the hag is seasonal on the British coasts, being found only in the end of spring or the beginning of summer, and then only in fine and tranquil weather. Altogether it is an animal of obscure history and habits, and its chief interest lies in the peculiar place which it occupies in the system, as partaking of the characters both of the vertebrated and the invertebrated animals.

There is another fish of a singular character, and nearly allied to this one, which we omitted to notice in its order in the alphabet, and therefore we shall introduce it here, as it forms an appropriate supplement to the species of which we have been speaking. The fish to which we allude is

THE LANCELET (*Amphicorus lanceolatus*). This fish is

of very diminutive size, scarcely an inch in length, very slender, and almost entirely transparent. The body is compressed laterally, and there are no pectoral, ventral, anal, or caudal fins, but only a single dorsal fin, extending the whole length of the body, but becoming almost rudimental at the tail, which is very sharp pointed. There are no eyes, and no vestige of any external organ, except a mouth, which is situated on the under side, a little behind what may be regarded as the nose or snout. This mouth is surrounded by small tentacula, and it opens and shuts laterally. It does not appear well adapted for adhering, as the mouths of the typical *Cyclostoma* do; but still the fish more nearly resembles them than it does any others. The surface of this curious little fish is entirely without scales, and the rays which support the dorsal fin are very numerous, though minute. The spinal column is not only cartilaginous, but almost rudimental; and yet the muscles, which are numerous and beautifully arranged, are so placed as to leave no doubt that the animal is a vertebrated one. The filaments, or tentacula, which surround the mouth, and which, like those of the hag, appear to be the only distinct and located organs of sense, are not inserted on the sides of the mouth, but on the os hyoides, or bone of the tongue; and thus the tongue appears to be the essential organ with it as well as with the former.

This singular fish is either very rare, or it is overlooked, only two specimens being mentioned. The first of these was obtained by Pallas; the second was obtained by Mr. Couch, sent to Mr. Yarrell, and by him described in his "British Fishes." Both were procured on the coast of Cornwall, and both, we believe, found accidentally.

NAPELLUS is the *Aconitum napellus* of Linnaeus, the common monkshood of gardens, of which there are several varieties. The aconites are among the most powerful vegetable poisons known. The root is the most virulent part of the plant; a single drachm has been known to cause death.

NARAVELIA (Decandolle). A hothouse climber belonging to *Ranunculaceæ*, formerly known as the *Atragene zelanica*. It is propagated by cuttings, and grows well in a mixture of sand, loam, and moor earth.

NARCISSUS (Linnaeus). An extensive genus of well-known bulbous flowers, mostly natives of Europe. Several of the species are British, the common daffodil being found wild in many places. The *N. tazetta* or polyanthus, jonquil, and the poeticus, are among the most esteemed of the tribe. The narcissi belong to *Amaryllidææ*, and are easy of cultivation.

NARTHECIUM (Mohr). A genus of small rush-like plants found on turf bogs, belonging to the sixth class of sexual botany, and to the natural order *Juncææ*. One species is indigenous to Britain, another is found in North America.

NASTURTIIUM (Dr. Brown). A genus of annual and perennial herbs, chiefly aquatics. The flowers are tetradynamous, and consequently belong to *Cruciferaæ*. The watercress is the principal one cultivated. The *N. officinale*, the common one, is brought in immense quantities into the metropolis, being collected from the neighbouring streams, and forms an important though humble branch of domestic commerce.

NASTUS (Jussieu). A reed-like plant, found in Cumana, belonging to *Graminææ*, formerly called

Bambusa latifolia by Humboldt and Bonpland, but made a separate genus by Jussieu.

NAUCLEA (Linnæus). An East Indian genus of trees and shrubs, belonging to *Pentandria* and to the natural order *Rubiaceæ*. Generic character: flowers in a close head; calyx of five teeth persisting; corolla funnel-shaped, elongated; limb five-cleft; anthers almost sitting, and inserted into the sinus of the limb; style long and protruding; stigma headed. Fruit drupaceous, united in a double berry; berries many-seeded. These are store plants, and succeed and are increased in the ordinary way.

NAUCORIS (Geoffroy). A genus of aquatic hemipterous insects belonging to subsection *Hydrocorisa*, and family *Nepidæ*, having the body of an oval subdepressed form, without any terminal filaments; the antennæ minute and four-jointed; the fore legs raptorial, and the four hind legs ciliated and well adapted for swimming; the posterior tarsi two-jointed, and with two ungues. There is but a single British species, *Nepa cinnicoides* (Linnæus), which is about half an inch long, of a greenish-brown colour, with the head and thorax brighter coloured. It is of common occurrence in ponds and stagnant waters; is very active, and well fitted for preying upon other aquatic insects, its beak being short and robust.

NAUTILUS (Linnæus, Lamarck). This very elegant mollusc is so generally well known to every collector of shells, that a very detailed description would be superfluous. Its form is spiral, discoid, the whorls contiguous, the last enveloping the others; numerous cells, separated by a thin pearly partition, or transverse septum, concave on one side, and perforated by a syphon running through them all. Some species are umbilicated, but none are known to be mammillated. In the fossil species the divisions of the cells form external ribs, and assume a great variety of sculpture; but in the recent species these divisions are but slightly visible; and when the shell is divested of its exterior coating, and the pearly substance displayed, no trace of these separations can be discovered. The animal inhabiting this mollusc only occupies the last open division of its shell, being attached to it by means of a tendinous or muscular appendage, which passes into the syphon; the mantle is obliquely opened, and prolonged into a kind of hood above the head, which is provided with tentacular appendages, as if digitated, and surrounding the aperture of the mouth. In the fossil genera of the *Nautilacæ* two syphons are found to penetrate the cells, but we do not know of any living species presenting more than one. This mollusc, from its graceful form, and the beautiful prismatic pearly appearance it exhibits when the external coloured coating is carefully taken off, has been known to naturalists from the earliest period. Artists have exercised their graphic skill in ornamenting it with landscapes, historical and mythological engraved subjects; and in the accounts given of some of the costly articles of regal splendour, we read of these shells being mounted, as drinking cups, in gold, bedecked with jewels. In our times specimens of the *Nautilus*, thus exquisitely fashioned, have sold at high prices, and are to be seen in the cabinets of the wealthy amateurs of the fine arts. Much speculation of opinion exists as to the habits of this mollusc, which is described as sailing before the wind like a vessel; and it is by some conjectured that the empty cells contain air or water, which the animal can volun-

tarily expel, so as to render its habitation sufficiently buoyant to rise to the surface of the waters. Other naturalists are of opinion that the shell is nearly enveloped in the mantle, and the animal carries it on its back in the manner of the snail, crawling habitually at the bottom of the sea, which it only quits from peculiar circumstances of necessity or convenience. The late lamented Mr. Bennet captured one of these animals attached to its shell; and that eminently talented zoologist, Professor Owen, has published a most elaborate and interesting description of its structure, which we will not mutilate by partial extracts. A singular part of its formation is what has been termed the beak, that is, a hard portion resembling the parrot's beak, by means of which this mollusc possesses the faculty of crushing smaller shells, crustacea, &c., indicating its being carnivorous. A transverse section of this shell exhibits one of the most beautiful examples of nature's mathematical symmetry that can be witnessed; and *en passant* we will take this opportunity of suggesting the propriety of sectional specimens of the genera of molluscs, to exhibit more fully their structure. The author of this article has many specimens, but there is no complete series. Where they should be found, the British Museum, they (like many other things necessary to science) are not, and the department of malacology is there an instance of "confusion worse confounded." Under the article **AMMONITES**, the fossil gigantic species of a former creation are described.

NAVICELLA (Lamarck; *NERITA*, Chemnitz). These molluscs are nearly allied to the genus *Nerita*, but yet more closely to the *Neritina*. They are fluviatile or fresh-water shells. The summit does not turn in an oblique spiral curve, as in the genera mentioned to which they are allied; it is straight, turned quite to the base, and concave beneath; the left margin flattened, sharp, and straight, forming a flat internal partition resembling a half-decked boat, though this does not ever cover *half* the aperture of the shell; it has an epidermis, and is closed by a solid, flat, thin calcareous operculum, with one lateral and subulate tooth or apophyse. Their habitat is in the Indian Archipelago, and the animal is carefully figured in the Zoological Atlas to the Voyage de l'Uranie. This mollusc is classed in the fourth family *Hemicyclostoma*, second order *Asiphonobranchiata*, second class *Paracephalophora*.

NEBRIA (Latreille). A genus of coleopterous insects belonging to the family *Carabidæ* and subfamily *Carabides*, having the body of an oval-oblong and flattened form; the thorax cordate truncate, the palpi short; the mandibles not dilated externally, as in *Leistus*; the body generally furnished with wings, and the three basal joints of the anterior tarsi dilated in the males. These are handsome terrestrial insects generally found on the sea-coast; the type being the *N. complanata*, of a buff or clay colour, with black markings. Dr. Leach has separated some species under the name of *Helobia*, including the very common *Carabus brevicollis* of Fabricius; whilst Bonelli has detached the apterous species, which he has named *Alpeus*.

NECROBIA (Latreille). A genus of coleopterous insects, belonging to the family *Cleridæ*, having the antennæ terminated by a three-jointed club, of which the joints are not closely fixed together; the four palpi are terminated by an enlarged triangular

or hatchet-shaped joint, and the thorax has no anterior transverse impression. These are small gaily-coloured beetles, found chiefly in the neighbourhood of decaying heaps of bones: they creep slowly, but fly with agility. There are three British species, including the *N. ruficollis* (Olivier), which is of a violet-blue colour, with the thorax, base of the elytra, and legs red. This insect is widely distributed, being found throughout the Old World from the west of Europe to the East Indies; a peculiarity doubtless attendant upon its natural habits. This insect is especially worthy of the regard of entomologists from its having been the means of saving the valuable life of Latreille. During the sanguinary period of the first French revolution, when "la fanatisme révolutionnaire," as Latreille himself had the boldness to style it, was at its height, this good man, as his writings fully justify us in styling him, was thrown into prison, and doomed to an inevitable death. In his prison he discovered one of these insects, which he sent to a young friend of talent, who made use of this simple circumstance as a proof of his disregard of political feelings, and obtained his release through the medium of M. Dargelas, of whom, as well as the former (M. Bory de Saint Vincent), he has, on many occasions, spoken with gratitude in his various works.

NECRODES (Wilkin). A genus of coleopterous insects, belonging to the section *Pentamera*, and family *Silphidae*, having the hind legs thickened and bent, especially in the males; the body is oblong-depressed; the thorax sub-orbicular; the antennæ longer than the head, terminated by a five-jointed club. There are several species of this genus found in different parts of the world; one of which is not of uncommon occurrence in this country, feeding on carrion washed on the banks of rivers. It is the *Silpha littoralis* (Fabricius), and is subject to considerable variation in size and in the form of the hind legs. Dr. Leach has named one of these varieties *N. Curtisii*.

NECROPHORUS (Fabricius). A genus of large and handsome coleopterous insects, belonging to the family *Silphidae*, having the body of an oblong form; the antennæ terminated by a distinct perfoliated mass, not longer than the head; the thorax broadest in front, the elytra truncate behind, and the anterior tarsi dilated in the males. These insects have obtained the name of burying-beetles, from the peculiar

instinct which they exhibit of burying the dead bodies of small animals, such as moles, mice, frogs, &c., as a receptacle for their eggs and larvæ. Their powers of perception are very strong, and it is surprising how soon they discover a dead body fitted for their purpose, round which they may be observed flying with the elytra elevated, their dorsal surfaces being applied together. They soon creep beneath the body, and commence scratching up the earth from the sides and under the animal, which, by degrees, descends into the pit which is thus gradually deepened; when it has reached a sufficient depth the earth is thrown over it, and the insect deposits its egg upon the car-

case, so that the larva, when hatched, finds itself in the midst of a repast, disgusting enough, but suited to its taste. The larva is long, of a dirty white colour, with the upper surface of the anterior segments armed with a scaly plate of a brown colour, and with small elevated points upon the hinder segments. They have also six scaly legs, and the jaws are robust. When they have attained their full size they bury themselves still deeper into the earth, where they construct an oval cell, the inner surface of which they coat with a gummy secretion. These insects, like many others which feed upon carrion, have a strong odour like musk. The habits of these insects have been especially studied by M. Gleditsch, and more recently by various persons in France who have written upon the subject of destroying moles, and by whom various points in their economy have been elucidated.

There are a considerable number of species of this genus, some of the largest of which, *N. grandis* (Fabricius), we have received in some numbers from North America. There are seven British species, five of which are distinguished by the golden-coloured bands upon the elytra; these species vary amongst themselves in the form of the thorax, the structure of the hind legs, the markings on the elytra, and the colours of the club of the antennæ. One of the most common species is the *Silpha vespillo* (Linnaeus), in which the posterior tibiæ are curved, and the trochanters furnished with a strong spine. The species vary also in length, from half an inch to one inch and a third, which is the length of *N. germanicus*, the largest and rarest of the British species.

NECTARINE is the *Persica laevis* of Decandolle, a subvariety of the common peach; the only difference being that, whereas the skin of the latter is downy, that of the nectarine is smooth. In fact, they are frequently found on the same tree; so that there can be no reason for making those fruits distinct species. They are both cultivated and propagated in the same manner, and are both deservedly esteemed as among the finest of our exotic fruits.

NECTOPODA is De Blainville's first family of the fifth order *Neuleobranchiata*, second order *Polybranchiata*, second class *Paracephalophora*. The animals of this family may generally be described as possessing an abdominal foot, compressed into a rounded swimming appendage. The genera *Pterotrachea* and *Carinaria* constitute the family.

NECYDALIS (Linnaeus; *Molorchus*, Fabricius). A genus of coleopterous insects, belonging to the section *Tetramera*, and family *Cerambycidae*, in which the elytra are short and truncated at the tips, covering only the base of the abdomen and wings. Linnaeus, indeed, introduced into the genus other species, in which the elytra do not meet in a straight suture down the back, but are of an elongated conical form; but, except in this particular, there is no relation between these insects. The antennæ are long, and the femora thickened at the tips. These insects are found upon flowers, and upon the trunks of trees. From the introduction of other species by Linnaeus into the genus, some confusion has arisen in the application of the name which is applied by the French to the longicorn species, which Fabricius (followed by English authors) called *Molorchus*, and applied the name of *Necydalis* to the *Edemeræ* of the French.

NEGUNDO (Moench). A genus of North American trees, belonging to the natural order *Acerineæ*. They were considered by Linnaeus as maples, and he

called them *Acer negundo*; but they have been erected into a new genus by Moench. They have been long in our ornamental plantations, and known as the ash-leaved maple, and arrive at considerable bulk in sheltered situations; for if much exposed they are liable to be shattered by the wind.

NELITRIS (Gærtner). A fruit-tree found on one of the Society Islands. It was first named by the younger Linnæus, *Paidium decaspermum*, but now *N. Jambosella*. It belongs to *Myrtaceæ*, and is easily grown and propagated on the stove.

NELUMBIUM (Jussieu). A highly ornamental genus of aquatic plants, natives of warm climates. This and other plants of similar habits form the natural order *Nymphæaceæ*, commonly known by the name of water-lilies. The *N. speciosum* is supposed to be the sacred bean of the Egyptians; though now no longer found in the Nile, that river formerly abounded with it; and, as both its tuberous roots and seeds are edible, was of great use to the inhabitants. It is very common over all the eastern parts of Asia. The numerous canals of China are filled with it, its tubers being universally used as a culinary vegetable. The flowers are splendid; and it is held in high estimation by the Chinese, and in that empire it retains a share of the sacred character it formerly held in Egypt.

NEMATOPODA (De Blainville; *LEPAS*, Linnæus; *CIRRHIPODA*, Lamarck and Cuvier). Lamarck separated this class into two orders; those molluscs which were attached to any object by a peduncle or membranous tube, and such as were permanently affixed from the moment of their birth to rocks or other submarine bodies. This class forms the sub-type *Malentozoaria*, or the *Mollusc articulata*, a group which corresponds with the multivalve molluscous worms of Linnæus, and the disciples of his school, separating the *Pholas* and *Teredo* from them, they being true lamellibranch molluscs. Lamarck was doubtful whether to place these animals as the first order of his class *Crustacea*, under the name of sightless crustacea, or to assign them a place at the end of the *Mollusca*. They nearly resemble the former, since we find the *Cirrhipoda* furnished with the same system of nerves, with jaws analogous, and their tentacula resembling those of the shrimp. They now, however, stand in the system of modern writers as following the *Mollusca*. The first class includes the first family *Lepadicea* or *Anatifa*, containing the genera *Lepas*, *Gymnolepas*, *Pentalepas*, *Polylepas*, *Litholepas*; second family *Balanides*, contains the genera *Balanus*, *Ochthosia*, *Conia*, *Creusia*, *Chthamalus*, *Coronula*; the second class is called *Polyplaxiphora*, and is formed by the genus *Chiton*, which may be considered totally distinct from all the rest of the animal series, and forming the transition from the cephalopod molluscs to the chetopods of the type *Entomozoaria*.

NEMOPTERA (Latreille). A remarkable genus of neuropterous insects, belonging to the family *Panorpida*, having the abdomen destitute of the curious claw with which it is armed in the males of *Panorpa*, but especially distinguished by the form of their posterior wings, which are many times longer than the body, very slender, and more like feathers than wings. The species are found in Portugal and Africa; the type of the genus being the *Panorpa coa* of Linnæus, having yellow wings, with black spots. The writer possesses several undescribed species from the Cape of Good Hope; and Dr. Klug

has informed him that he is preparing a monograph upon the group, in which the Berlin Museum is very rich.

NEMOSOMA (Desmarest). A curious genus of coleopterous insects belonging to the group termed *Xylophaga* (or wood-eaters) by Latreille, and placed in the family *Engideæ* (which see for some observations upon the natural situation of these insects). The body is long, slender, and cylindric; the head notched in front; the mandibles strong and protruded; the tarsi long and slender. There is one species of this genus, *N. cylindricum*, a pretty insect of small size, found, but very rarely, under the bark or stumps of trees, palings, &c.

NEOTTIA (Swartz). A genus of curious herbaceous plants, natives of many different parts of the world. The flowers are gynandrous, and of course the genus belongs to *Orchideæ*. Two of them are natives of Britain, viz. *N. nidus avis*, bird's-nest orchis, and *N. spiralis*, ladies' tresses of English botany. The first is found in damp woods, and the second on chalky pastures.

NEPENTHES (Linnæus). A genus of two species of curious half-aquatic Chinese plants, belonging to the natural order *Cytinææ*. These plants are remarkable for having the points of the leaves formed into pitchers of a considerable size, with a neatly-fitted lid, with a hinge. They are cultivated as curiosities in our stoves, planted in turfy-peat soil, with the pot constantly kept in a pan of water, and in a pretty high temperature.

NEPIDÆ (Leach). A family of aquatic hemipterous insects, belonging to the section *Hydrocorisa* of Latreille, having the antennæ minute, and inserted beneath the eyes, by which they are concealed from above; the tarsi are composed of two joints only; the eyes of large size; the anterior legs in the form of a claw, the femur being large, and channelled on its under surface, in order to receive the interior part of the tibiæ, which shut upon it in the same manner as in the *Mantidæ*; the tarsi are very short, and sometimes connected with the tibiæ, so as to form one piece. This structure indicates the raptorial character of the family, which consists of insects of large or moderate size, which are all inhabitants of the water, and which feed upon other aquatic insects, which they seize by the assistance of their fore legs, and convey to the mouth, which consists of a short, but acute and strong articulated proboscis, with which they are enabled to inflict a smart wound. The family corresponds with the Linnæan genus *Nepa*, and which have obtained the name of water-scorpions, in allusion to the form of the fore legs, which are somewhat similar to those of the scorpion. The genera of which this family is composed are *Galgulus*, *Naucoris*, *Belostoma*, *Nepa*, and *Ranatra*, and several others recently established by Messrs. Laporte and Burmeister, the second, fourth, and fifth, being inhabitants of this country. The genus *Naucoris* is described in its alphabetical situation; that of *Belostoma*, Latreille, is distinguished by having the abdomen terminated by two setæ; the tarsi are two-jointed, and the antennæ are dilated at the side into a comb. This genus comprises several exotic species of very large size, some of them being, in fact, nearly six inches in expanse, as in *Belostoma grandis*, Fabricius. The genus *Nepa*, Linnæus, has the anterior tarsi composed of a single joint, and the four posterior or tarsi two-jointed; the antennæ

furcate; and the anterior femora are thick; the abdomen is elliptic, and terminated by two setæ. The body of *Nepa cinerea*, Linnaeus, the type of the family, is represented (with the limbs and anal setæ cut off near the base) in the article INSECT, vol. ii., p. 870, in which the respiratory apparatus of the insect is exhibited from the invaluable work of M. Leon Dufour. This insect is about two-thirds of an inch long, of an ashy colour, with the upper surface of the abdomen red, and the anal setæ shorter than the body. This is a very common species, found in all stagnant ponds, &c.; it is very slow in its motions. The eggs are of a curious form, each having a series of terminal points, which bend upwards, and form a kind of cup for the egg placed above (see fig. 10, article INSECT, vol. ii., p. 884).

The genus *Ranatra*, Fabricius, having the *Nepa linearia*, Linnaeus, for its type, is distinguished by its very narrow form, the rostrum porrected, and the anterior thighs long. The typical species inhabits this country, but is a local insect; it is about an inch long, with the anal setæ as long as the body. It is beautifully figured, with its details, in Mr. Curtis's British Entomology. We have met with it in considerable numbers in one of the ponds on Wandsworth Common.

NERINA. A genus of molluscs established by De France, but reunited to the genus *Cerithium* of other naturalists.

NERITA (Linnaeus, Lamarck, Cuvier). The true genus *Nerita* may be distinguished from the *Neritina* by the following characters, independent of its being a marine shell. It is solid, semi-globular, concave beneath, and not umbilicated; the aperture is entire, semicircular; the summit very obtuse, left side flattened and septiform, sharp, and often denticulated; the inner one slightly concave, generally with granulations; the operculum constantly calcareous and subspiral, the summit of it marginal at the left extremity, with one or two apophyses of muscular adhesion on its posterior edge, opening as the animal protrudes its body, and closely shutting when the animal is at rest. These shells are never spined, but are variously striated or sculptured; and Lamarck distinguished them into the marine and fluviatile species, on a consideration of the thickness of the shell, which in the former is greater than in the latter, and by the denticulated edge of the right side, which does not exist in the second. We, however, agree with those naturalists who derive a more constantly distinguishing character from the external sculpture of the operculum—a guide we have pointed out in the leading article of CONCHOLOGY, as one to be depended upon, but hitherto not sufficiently examined; under OPERCULUM we shall enlarge upon this circumstance. There are about nineteen species of marine *Nerites*, and twenty-five species of fluviatile *Nerites*, or, as we have separated them, *Neritina*. In the present genus, as constituted by De Blainville, a well-defined arrangement exists, including various genera of other authors. The first division includes such as have only one medial tooth on the left edge, called by Oken *Petoronta*; the second species have two teeth, and the third three or four; Lamarck's *Neritina* are without any teeth. Another species forms Sowerby's *Pileolus*. These molluscs principally inhabit the Eastern and American seas and rivers, two only of them being European. Fossil species are not numerous.

NERITINA (Lamarck). A genus of molluscs, see the article NERITA, from which it was separated

by Lamarck, on account of its being a fresh-water shell, and the thinness of its texture. They are also sometimes armed with long spines, and variously coloured externally.

NETTLE. See URTICA.

NEUROPTERA (Linnaeus). An order of winged insects, belonging to the division having the mouth formed with mandibles for mastication, and chiefly distinguished by the structure of the wings, which are naked; that is, not enclosed by elytra or tegmina, but often having the anterior and posterior pairs of equal size, and furnished with a great number of nerves, which gives the wings the appearance, under the microscope, of a piece of the most beautiful net-work; whence, indeed, the name of the order is derived, *neuron* signifying a nerve, and *pteron* a wing; the membrane enclosed between these nerves is very fine and transparent, often exhibiting a reflection of the prismatic tints, or marked with spots or bands of various colours. The situation of these organs during repose is various; in some they are horizontally extended at right angles from the body, as in the larger *Libellulidae*; in others, as in the smaller species of the same family, their inner surfaces are applied against each other; whilst in the *Perlidae* they lie flat upon the back, or are deflexed at the sides like the roof of a house, as in *Hemerobius*, *Psocus*, &c. In many species the wings are of equal size, as in the dragon-flies, *Panorpa*, &c.; in others the posterior pair are considerably smaller than the others, especially in the *Ephemeridae*; in which, indeed, the posterior wings occasionally are entirely evanescent. In *Nemoptera* the posterior pair are much longer than the anterior, and very slender.

These insects have the head of a large or moderate size, the eyes, which are lateral, sometimes occupying nearly the whole of this part of the body; the ocelli are placed on the forehead; the latter are, however, wanting in some species, as in *Myrmeleon*, *Osmylus*, &c.; the antennæ are frontal, and of very different forms, being very short, and resembling a fine bristle, in the *Libellulidae* and *Ephemeridae*; long and clubbed in *Ascalaphus* and *Myrmeleon*; and filiform or setaceous in the others. The mouth consists of the ordinary organs composing a mandibulated mouth, the maxillæ being very robust, and the tongue well developed, in the dragon-flies. In some species, as the *Perlidae*, *Hemerobidae*, &c., the construction of the trophi is almost identical with that of the *Orthoptera*. In the *Ephemeridae*, which are destined to live but a day in the final state, the mouth is rudimentary and almost obsolete. In the dragon-flies the palpi are also very minute, whilst in the *Myrmeleonidae* they are long and slender. In the *Panorpidæ* the front of the head is prolonged into a kind of rostrum, at the extremity of which the trophi are placed.

The legs of these insects are of a moderate size, flight being the chief mode of locomotion in the imago state; the legs do not acquire that degree of development which we find in some of the cursorial and saltatorial species; the tarsi vary in the number of joints in the different species, there being five in the *Hemerobii*, *Perla*, &c., four in the *Raphididae*, three in the *Libellulæ*. In all they are terminated by two small hooks. The abdomen is long, cylindrical, or compressed, with the segments distinct, and terminated in the males of many species by hooks which are employed during coupling. In some species both sexes are provided with two or three very long and

slender hairs or bristles, as in the *Ephemera*, whilst the female *Raphidia* has a single long and sword-like appendage. In none of the species, however, do we find any instrument acting as the sting of the *Hymenoptera*.

There is considerable diversity in the transformation of this order; the larvæ are hexapod, and very variable in their habits and habitations. Many of them reside in the water, where they are either predaceous or vegetable feeders, some few feeding upon decayed plants, others in holes which they form in the sand. The majority are carnivorous, and feed upon other insects; the aquatic species are provided with an apparatus for obtaining a supply of fresh air, which has some resemblance to lateral series of external gills, but which are, in reality, the tracheæ greatly dilated externally. The pupæ are as active as the larvæ in the dragon-flies and some other species; but in both these states of these insects the mouth undergoes a remarkable modification of form. In the *Ephemeridæ* there is another curious modification in the transformations, as described in our article upon that family. In some the pupa state is inactive, and enclosed in a cocoon formed by the larvæ, as in *Hemerobius*, *Myrmelcon*, &c. The *Termitidæ*, or white ants, offer as curious an instance of departure from the type of the order as do some of the *Apidæ* in the order *Hymenoptera*, there being three kinds of individuals exclusive of the active larvæ and pupæ. The transformations of *Panorpa* are unknown. In the imago state the duration of life is variable, some species, as many of the *Ephemera*, being but the creatures of a day, or even still less. There is also very considerable diversity in the size of these insects; some of the *Libellulidæ* being amongst the largest of our insects, whilst some of the *Hemerobiidæ* or *Psocidæ* are very minute, but not so minute as the smallest *Hymenoptera* or *Coleoptera*.

From the considerable variation, both in structure and transformations of these insects, there has been a considerable diversity of opinion relative to the extent of the order, the *Libellula* and *Ephemera*, having an aquatic pupa, being regarded by some authors as the types of distinct orders. The same has also been maintained respecting the *Termitidæ*, or white ants, and the caddice flies (*Phryganæ*), which last have been formed by Mr Kirby into the order *Trichoptera*, whilst by Latreille, the order is maintained in its Linnæan extent. We have adopted the views of modern English authors, separating only the *Phryganæ*. The order is therefore divisible into sections, which exhibit the following succession of natural relations founded upon the habits and transformations of the groups:—1. Carnivorous insects, having aquatic larvæ and active pupæ, bearing a certain resemblance to the imago; 2. Carnivorous insects having terrestrial or aquatic larvæ and incomplete pupæ; 3. Carnivorous or omnivorous insects, terrestrial in all their states, and having active pupæ differing from the imago only in wanting wings. Latreille, by introducing the *Phryganæ* into the order (and which correspond with the *Ephemera* in the aquatic habits of the larvæ and the rudimental structure of the mouth of the imago, and forming together Dumeril's family *Agnatha* or *Buccelles*) adds a fourth group of herbivorous insects, with aquatic case or caddice-forming larvæ, and inactive, incomplete pupæ; terminating the order with those species

of *Phryganæ* which have the wings very slightly reticulated, resembling, in many respects, some of the least perfectly organized *Lepidoptera*. This last relationship is admitted by most recent authors, so that the neuropterous insects may be arranged with the *Trichoptera* on one side, leading to the *Lepidoptera*, whilst, on the other side, they are allied to the *Orthoptera*, as above noticed; the *Trichoptera* again are allied to the *Tenthredinidæ* in the order *Hymenoptera*, which renders it impossible to place these orders in a continuous series in regard to their affinities.

The order *Neuroptera* is divisible into the following sections and families.

1. *Subulicornes* (Latreille). Having the antennæ minute and setiform, with not more than seven joints; eyes large; ocelli two or three; larvæ aquatic; pupa resembling the larva; imago aerial.

A. *Odonata* (Fabricius). Wings of equal size; mandibles very large; respiration of the larva anal. Genus, *Libellula* (Linnæus).

B. *Anisoptera* (Leach). Posterior wings small; mandibles rudimental; respiration of the larvæ by means of lateral pseudo-tracheæ. Genus, *Ephemera* (Linnæus).

2. *Filicornes* (Latreille, *Planipennes*, Règne Animal). Antennæ long; filiform setaceous or clavate, much longer than the head; multi-articulate; eyes moderate; ocelli sometimes wanting; larvæ generally terrestrial.

A. Tarsi five-jointed. Linnæan genera, *Panorpa*, *Myrmelcon*, *Hemerobius*.

B. Tarsi four-jointed. Linnæan genera, *Raphidia*, *Termes*.

C. Tarsi two or three jointed. *Termes*, *Psocus*, (Latreille).

D. Tarsi three-jointed. Genus, *Perla* (Geoffroy).

Each of which genera constitutes the type of a modern natural family.

NICANIA. The late lamented naturalist and amiable man, Dr. Leach, constituted this genus, in consideration of the peculiar formation of the hinge, and its manner of interlocking the valves. This mollusc is, however, now placed as a species of the genus *Venus*, the animal not differing sufficiently from it. The philosophical and accurate views of Dr. Leach sometimes led him into distinctions occasionally too nice in the classification of testaceous mollusca. This is no fault in principle, but leads to great inconvenience, by the multiplication created in the number of genera.

NICOTIANA (Linnæus). A genus of herbaceous annuals, mostly natives of America. The flowers are pentandrous, and the genus belongs to *Solanæ*. Few plants have been more regarded than the *N. tabacum*, for an account of which see TOBACCO.

NIGHTINGALE (*Motacilla lusciniæ*, Linnæus; *Curruca lusciniæ*, Bechstein). Under the word SYLVIA, in the alphabetical order, there will be found a general notice and arrangement of those small forest birds, chiefly summer visitors, which make the early part of the season so cheerful, especially in the southern and warmer parts of Britain; but the nightingale has been so long celebrated, and is so local as a British bird, that we shall insert a very brief notice of it here, including some extracts from Bechstein's *Cage Birds*, because in Germany, where he observed and studied, nightingales are much more common,

and singing birds of all descriptions much more attended to, than they are in this country.

The nightingale is a bird of many names, and some others of the migrant birds of song are called nightingales, or, at least, by the popular names which the nightingale receives in different parts of the world. It is the *Philomela* of the ancients; that is, the bird that "loves darkness." This love of darkness is, however, not absolutely correct. During the period of its natural song, the nightingale does indeed sing later in the evening and earlier in the morning than any of its fellow-choristers of the grove; but there is, in some places at least, a silent hour or two in the dead of the night when the voice of the nightingale is not heard; but it always begins between dawn and sun-rise, and generally very near the first. It does not appear, however, to be partial to the chattering notes of many other birds. In the early time of fine summer mornings nothing can be more delightful than the *revellio* of the nightingale, when one is lying quietly in bed, with the window open, and no sound heard save that of the bird. The volume which it pours forth upon these occasions appears absolutely to make the air shiver and thrill, even though the songster is a furlong or two distant; and if two or more, posted in different parts of the grove, sing against each other, as is very often the case, their songs, which fall upon different parts of each other like a glee set for several voices, have a very pleasing effect. What may be the signal for nightingales giving over their song in the wild woods, we have had no means of ascertaining; but, in those which frequent groves surrounded with houses we have generally, if not invariably, found that the chattering of the house-sparrows puts an immediate stop to the music of the nightingales, even while the nightingales are in the woods, and the sparrows on the house-tops. We do not, of course, pretend to say that the din of the sparrows is the real cause of the silence of the nightingales, or that there is any tendency on the part of the latter to scorn the contest with such tuneless chatterers; but we have observed the fact during a succession of too many mornings for its being merely accidental in any one of them. It seems, indeed, that, however the aversion may operate, there is an aversion to singing, in a state of nature at least, in nightingales, if they have not all the song to themselves. We have heard them put to silence by a wild duck, scared from the ground within their hearing; and they do not sing when the wind is so strong as to rustle the leaves and shake the branches against each other, or when the rain falls in heavy drops, and makes its well-known pattering sound. In some situations, at least, the singing at night is prolonged into greater darkness than that at which the morning song commences; but this, of course, differs according to circumstances. While these birds continue their notes (and during the hours of song there are but few pauses), it is clear that they can neither seek food for themselves, nor contribute either to the nourishment or the accommodation of their young. How much of the duty of attending to these may devolve on the female nightingale we cannot say; but it is by no means unlikely that their songs, as well as those of many other birds, are delivered for the purpose (not with the *intention* on their part) of stimulating the female to the energetic performance of some duties. They are certainly not mere love-notes, affecting the nuptials of the birds,

and nothing more; for they extend over much of the hatching time, and do not cease when the young have broken the shell. Singing birds, from their numbers, the variety of their notes, the seasons with which they are associated, and a variety of other circumstances, which, though they do not come within the category of mere calculating economy, have yet a wonderfully rousing effect upon the minds and the activity of mankind, are highly interesting creatures. Their singing is the most interesting circumstance about them; and therefore it were highly desirable that those who have opportunity, inclination, and leisure, for studying the manners of birds in something like a satisfactory way, should pay particular attention to how the female bird is employed when the male bird is engaged in what may be called the family music. It has been observed that the females of various other birds are strongly excited by the voices of the males when there can be no possible influence of pairing in the case. The crowing of the common domestic cock, or of any other of the gallinaceous birds, is not a love-note, but rather a song of triumph for the overcoming or avoiding of some real or apprehended danger. The love-notes of that order of birds are soft and low; and it is probable that those of most other birds, and of mildly-disposed animals in general, are of the same character. The loves of the cats, indeed, seem, as Bottom says, to be the enactment of "a part to *tear* a cat in;" though that is not exactly the result. We are but little acquainted with "the loves of the lions," but it is not probable that roaring at the "top of his bent" is even the lion's mode of courtship.

This is a very curious subject altogether, and one to which nobody has yet done anything like justice; and justice cannot be done to it without a great deal of the most close and judicious observation, without which mere speculations would avail but little. There is no doubt that the working out of results in natural history must be in great part speculative, as is the case in everything else; but this speculation must follow the observation of the facts, and not go before it. To return, however, to the analogies of the birds. Many persons must have observed the absolute inspiration, as it were, with which a brood hen is stimulated to courage by hearing a cock crow in the moment of danger. A brood hen is naturally brave enough; but the sound of the crowing transports her into a perfect fury, even when her maternal attachment is still wholly absorbed by her young brood; and it is by no means improbable that the notes of the singing birds may, in part at least, answer some such purpose, though their enemies, at least when in the trees, are much less formidable, even in proportion, than those with which the hen has to contend in the protecting of her chickens.

Naturalists have not been wanting who have advanced the opinion that there are more species, or, at all events, varieties of nightingales, than one; and that, besides differences of colour and size, there are day-singers and night-singers, as distinct varieties, which continue their different hours of song at least for two or three generations. Now, the differences of colour in nightingales are never very great; and the differences of the two sexes in this respect are less than perhaps those of any other song birds; so that it is probable that these, as well as the slight differences of size, are occasioned by differences of locality; for there is scarcely any species of bird

which does not show more differences in this respect than the nightingale.

If we can draw any conclusions with regard to the habits of birds in a state of nature from what we can observe in a state of confinement, we should not be inclined to reckon the nightingale as coming under the description of a night bird in any of the ordinary senses of that term. In confinement it is so far from being a lover of the dark, that it is impatient of a dingy or gloomy apartment, and it is equally impatient of impure air—the favourable spot for its cage being a cheerful one near an open window; and it languishes in health, and the colour of its plumage fades, if it is kept in the dark. These are certainly anything but characteristics of a bird which loves darkness, though we never can draw perfectly satisfactory conclusions from observations made upon birds unnaturally kept in cages, because in this state those seasonal changes which have so powerful an influence in the economy of the bird do not, and cannot, operate. If the bird is, like the nightingale, a migrant, the cutting it off from its migration, and its changes of climate, must, to a considerable extent, affect the whole of its economy, because there are circumstances in the transference of the bird from climate to climate which cannot be compensated by any regulation of artificial temperature. There is also the grand change from the free air of heaven to a grated prison in a limited apartment, and this would be of itself enough to change the habits of most animals. If, therefore, we wish to obtain correct knowledge respecting the nightingale of nature, we must observe it pursuing its natural instincts in its own way.

The peculiar manner in which the nightingale is localised shows us that natural circumstances have far more influence upon it than they have upon most other birds which pass over the same range in their migrations. Most of our other summer birds, in so far as they do come, come pretty indiscriminately to surfaces of which the sub-soils are different, though each bird selects a particular kind of surface, or surface-vegetation, as more exclusively and appropriately its own. The nightingale, however, misses large patches of those countries which it visits in the summer, and there is always something peculiar in the subsoil of these places. It is rare upon the clays, and never found upon the moor or the marsh, though, in situations favourable to it, it is most plentiful near the banks of streams and rivers. It does not appear, however, to have any particular partiality for the water, but only for the rich and close vegetation which is found near the banks of streams, and other clear and wholesome water, or perhaps rather for the insect food with which such places abound.

It is not a bird of the depths of the tangled forests, or found far in the interior of an extensive wood. The air of such a situation is neither favourable to the nightingale nor to that upon which the nightingale feeds; and it is one of the striking adaptations in nature that the effect of natural circumstances upon a bird is to impel it to that place where its food is best and most abundant; and such is the power of this, that there are some birds sent full five thousand miles, and back again, in the course of every season, chiefly by this means.

They appear to migrate farther northward in latitude in proportion as the summer is more dry; for they reach much farther north in continental Europe

than they do in Britain; and farther still in Siberia than in western Europe. With us they do not reach any part of the country which can be considered decidedly hilly, and rainy in summer; and the places which they miss, or where their numbers are comparatively few, are always more subject to showers than those in which they are abundant. In those parts of England where nightingales are most common, and where the soil and the surface are a good deal diversified, places may be observed to which summer clouds frequently find their way, and pour down rain when there is none in richer places at no great distance, and it will be found that the song of the nightingale is very rarely heard in those places, though it may be abundant a very little way off. In this way the nightingale becomes a very excellent index to the summer character, at least of those districts which it visits; and, as the summer character of places is really the important one, the nightingale is of no inconsiderable use as a guide in topographical knowledge. In districts near London, the cold gravel-caped heights, the clayey bottoms, which retain stagnant water, and close woods of considerable extent, are the chief places which attract the summer showers, and they are places of which the absence of the nightingale gives warning.

It is quite natural to expect that we should get some topographical information from this bird, because it appears to be one of the most sensitive of the feathered race that journeys into such climates as ours; and what we see on a small scale in our own diversified country, we can infer on a large scale with regard to foreign countries. Nor is it difficult to see the reason why the nightingale should avoid places where there is much humidity, and where the ground is sterile if high, and the vegetation is rank if low lying. Soft caterpillars and soft insects are the principal food of the nightingale; and these are always abundant in proportion as, with an equal store of vegetation, the place or the season is dry. The winds, or more strictly speaking the weather, during which the leaves of our trees and hedges suffer so much from the larvae of insects, are always dry; rain coming in time in a great measure prevents the injury, and checks it even when it has proceeded to rather serious lengths. On these, and many other points connected with the productions of the earth, the places most favourable for those productions, and their healthiness or unhealthiness during the particular season, the song of the nightingale may thus be turned to an artificial memory of no small value; and while its evening or its morning notes delight our ears, we may readily make it the means of informing our minds. With us the nightingale does not make its appearance very early, neither does it stay very late. The time differs a little with the season in every country; and the more northerly the country is, the arrival is always the later and the departure the earlier. Of course, the variations of the different years alter the time of the coming of this, and of all migratory birds; but, in those which stay for so limited a period as the nightingale, the extreme limit of the variation in time does not generally exceed a fortnight or three weeks.

They arrive in Italy generally during March, in the middle of Germany about the middle of April, in England towards the end of the same month; and they generally reach the extreme limit of their migration before the middle of May. In departing southward, September may be said to answer to April,

only reversed in the order, and October answers in the same manner to March. Some, however, linger beyond the general time of departure; but these may be regarded as strays, probably of the latest broods, which rarely, if ever, survive the winter in those countries where they have been left.

When the nightingales first arrive they do not resort to the groves, copses, and thickets, at least for a few days, but remain on the open ground in the vicinity; and it is at this time that they are most easily taken by the bird-catchers. It is said, however, that the female redstart is often captured and sold for the male nightingale; and thus, though the purchaser gets a bird certainly, he gets one which will not disturb him with its songs.

The general opinion is that every nightingale returns to the place where it was produced, if it survives the fatigues and casualties of the journey. This is extremely probable, because we believe it is the case with most birds; and if the actual locality has been so changed during their absence as to become unfit for their habitation, they choose a new one as close to it as possible. If the paternal domain is of limited extent, and the old male and his progeny return together, battles are said to ensue, in which the young males are generally driven off; but if, on the other hand, the accommodation has been improved so as to afford room and food for all, the old bird becomes the founder of a colony.

The nesting, and the appearance of the young birds, are so well described by Bechstein, that we shall quote the passage:—"The nest is in a grove or shrubbery, among thick branches in a thorn-bush, or the trunk of a tree tangled with climbing vegetables, and even on the ground if there is sufficient cover for it there. Its form is simple and inartificial,—dry leaves on the outside, hay on the inside, and fine roots, with the hair of animals, are all the apparatus. The female lays from four to six eggs, of a brownish green, on which she sits a fortnight. The young are fed with small caterpillars or butterflies. As the low position of the nest exposes them to become the prey of carnivorous quadrupeds, they soon quit it, even before they can fly. Their plumage before moulting has no resemblance to that of the old birds, except the red of the tail; the upper part of the body is of a reddish grey, spotted with yellowish white on the head and coverts of the wings; the under part is of a rusty yellow, spotted on the breast with dark brown; but after moulting the resemblance is so close that they can hardly be distinguished. If, therefore, any of these birds are caught towards the end of summer, they are carefully examined on the back of the head, round the eyes, and under the beak and neck, for, provided there remains in these places a small feather, or mere yellow point, it is sufficient to indicate that they are young. As these are the only means of judging, if no marks appear it is necessary to wait a few days till the bird begins to sing. This, however, is not a sure sign, as the young females sing as well as the males till the month of April, though in a weaker and more unconnected way, and without so visibly swelling their throats; it is by these nice observations that connoisseurs succeed in distinguishing them. It may also be remarked, as a hint to those who wish to rear nightingales, that, when in the nest, those which are marked with white, and especially those which have a white throat, are males; the reddest and brownest being

always females. The young, when taken, are fed with ants' eggs mixed with white bread, grated and moistened. The males begin to warble even before their tails are quite grown; if the father and mother are taken at the same time as the young ones, they will, when caged, continue to feed them as before. It is said that nightingales sometimes build in the bird-room; this, however, can only succeed by giving up to a tame healthy pair a whole room, in which a sort of grove should be formed of branches."—Cage Birds, pp. 296—7.

While engaged in the work of incubation, the female nightingale is represented as being a very close sitter, and not leaving her eggs more than once in the course of the day. Indeed, this single quitting of the nest seems to have for its object the preservation of the bird's health by exercise more than the mere finding of food. The male is understood to carry food to the female during this time; and to do it much more during the day than during that part of the night which is silent, at least with many of these birds. The nest is, however, generally placed in a secluded situation; and the birds, after they once betake themselves to their nesting-places, are so much concealed, that very little is known respecting them. They are understood, however, to be very voracious. They are known to be so in confinement; and consequently the finding of their own food, and that of their young, not only costs them a great deal of labour, but is very serviceable in destroying insects and their larvæ. They are particularly fond of the soft larvæ of the smaller ground-beetles, and also of the pupæ of ants, which are vulgarly termed ants' eggs, and collected on the continent as a sort of article of commerce in those countries where nightingales are eagerly sought after. Nightingales may be procured at three different times of the year. The first is on their arrival, and before they betake themselves to the cover of the woods and copses. The males come earliest, and are boldest; and they are very readily caught by those who practise the art of bird-catching. The next time of capture is from the nest, which requires a good deal of practice, and succeeds best at those times when the male is singing; but the young birds are delicate, and should not be removed too early. The last time of catching is just before they depart in the autumn; and at this season birds of the year are most frequently obtained.

In Britain nightingales are not very often kept in a state of confinement, because it requires a very strong passion for captive birds to overcome the trouble of attending to them. In Germany, however, where the attending of them is much more a sort of trade, they are often kept for a great number of years; Bechstein mentions five-and-twenty in one instance. In that country, or at least in some places of it, the taking of nightingales is prohibited, though probably more of them are taken in it than in any other country; and near the shores of the Mediterranean, where small birds are much in request as articles of food, nightingales are not unfrequently eaten.

In confinement nightingales sing for a much longer period than they do in a state of nature, sometimes continuing their notes from autumn till spring; for it very often happens that confinement changes entirely the season of song in birds, and especially in migratory ones.

The various methods of rearing, teaching, and

managing nightingales, do not so strictly belong to the proper natural history of the birds as to the particular art of the bird-fancier, and, therefore, those who wish for information on those particular birds will naturally seek for it in the various works devoted to the art. We shall therefore only farther notice very shortly the appearance of the birds, so that any one who chances to see a nightingale may know that it is one, and learn in how very sober a dress the sweetest songster of the groves is clad. The annexed cut will give some idea of the general shape of this songster.

The size of the nightingale varies a little, but its length is in general about five or six inches, of which the tail takes up rather more than two. The tarsi are long, adapting the bird for rather vigorous hopping along the ground, upon which a considerable portion of its food is found, both by poking and by scraping. Its bill is more than half an inch in length, and very slender, of a dull brown colour, but with a yellowish tinge at the base of the lower mandible, and the tarsi and toes are nearly of the same colour. The upper parts are yellowish-brown, with traces of reddish and sometimes greyish colour. The principal quills and larger coverts of the wings are dusky brown, with a reddish tinge on the margin of the feathers; and the tail, which is slightly forked, is darker brown, and more inclining to red. The sides of the neck, the ear-coverts, and the flanks, are pale ashen-grey, passing into white on the throat and the middle of the belly; and a very obscure dusky mark proceeds from the gape at each side toward the neck, and these pass into pale ash-grey on the breast, dividing the greyish-white on the throat from that on the belly. None of the colours are by any means decided; and there is nothing striking in the appearance of the bird. The female is but little different; but the tarsi are rather shorter, the head rounder, the eyes smaller, and the throat not so white.

Though nightingales feed chiefly, if not exclusively, upon animal matters during their breeding season, and though in consequence of this, independently of their delicate constitutions, they could not, in all probability, endure the winter with us, or indeed in any part of Europe, yet they are not absolutely confined to animal food, but betake themselves to soft berries for a supply before they leave the country, as is done by many others of the summer birds of song. When this is the case, they of course become, to a very considerable extent, tree-birds; but, in their characteristic season, they find great part of their food upon the ground, though they also pick many caterpillars from the leaves of the trees.

Though the nightingale is exclusively a bird of the eastern continent, to which nothing corresponding is found in America, yet, with the local exceptions to which we have alluded, it is pretty generally distributed over that continent, being found as far as the islands of Japan. In every land where it is met with the nightingale is a favourite with the people generally, and especially with the poets. The old story of its song being a lamentation uttered by the female when deprived of her mate is of course too ridiculous for requiring any formal refutation at the present day; but still, as there are a good many people fond of poetry, and but little conversant with natural history, and as birds, especially singing birds, are favourite themes with poets, it may not be amiss to put such in mind that the nightingale never sings in sorrow; that though the female does sing, it is but rarely, and in strains far inferior in power and compass to those of the male bird, which is always the nightingale of ordinary admiration and poetic description.

The music of birds, we need hardly say, is almost entirely produced at the bronchial end of the wind-pipe; and the muscles which give motion to that organ in the male nightingale are larger and more powerful, according to his size, than those of any other bird. The song of the female is also much finer than that of the female of any other warbler; and it is worthy of remark that the female is more like the male in the nightingale than in any other species. These great powers of song have not been given to the nightingale without an inclination on its part to put them into vigorous exercise. We have already mentioned the tendency which the chattering cries of less tuneful birds have to silence the nightingale; but it is evidently not from the love of silence, but from the want of sufficient stimulus in the rival sounds, that the nightingale abstains from singing on these occasions. In its native groves the nightingale rarely, if ever, sings against any other species of bird; and song-birds in general do not sing against those which have notes inferior to their own, though most, if not all of them, are prone enough to contend with superior songsters, especially if there is much resemblance between the songs and the localities of the birds. This propensity is of great advantage in the teaching of singing-birds, because, to the full extent of their powers, proper training enables them to imitate either the notes of birds naturally superior, or the notes of human music. There are many instances of the contention of nightingales for the palm of victory with human musicians; and these are recorded of nightingales in so many countries, that there can be little doubt of their truth. Bartolomeo Ricci calls on the nightingale as evidence of the great superiority of Silvio Antoniano, as an improvisatore, accompanying his spontaneous verses on the lyre when under the delightful temperature of an Italian evening sky. Silvio was charming the ears of the listeners by a very superior specimen of his art: a nightingale, attracted by the tones, perched close by, and sung in concert or in rivalry with the poet; upon which Silvio broke into an impassioned strain in praise of the nightingale, and touched his lyre with an effect which was perfectly magical. A similar occurrence happened at the *Jardin des Plantes* in Paris, although, as the human musician there was no improvisatore, the nightingale got no song of praise for its exertions. M. Gerardin was sauntering

in the garden on a fine evening, at that season when the nightingales are in most powerful song, and listening with delight to two which were singing against each other in the trees near him. He took his German flute, and, touching a few passages in tender airs, approached the spot whence the songs of the birds came. At first they were silent ; but he continued, and, before long, they accepted his challenge, and sung in a higher key than that in which he touched the flute. Gerardin raised his key a third, and instantly the birds raised their notes, still keeping above him. He then raised it an entire octave ; but, without hesitating a moment, the nightingales raised their notes still higher, and Gerardin, acknowledging that he was vanquished, put up his flute, and lingered to enjoy their song of victory.

In Moscow, at least before the conflagration of that city, which may have changed the eastern character of imperial palace, and paradise, and hovel, which it formerly exhibited, nightingales are tamed and taught in great numbers; and Dr. Clark states that what with the tamed birds, what with the wild ones singing in rivalry from the gardens and groves, the streets of Moscow were vocal with nightingales, as completely and as long continued during the night, as if they had been the groves of Italy, or the rose-clad bowers of Persia. In the last mentioned country, the nightingale is an especial favourite. The Persians are not only a highly poetical people, but their sylvan poetry is of a high and exquisite character. They therefore introduce the nightingale (the *Bul bul* in their language), more frequently than the poets of any other land. These allusions to it are natural too, and partake little of that romance which our poets have borrowed from the fables of the ancients. The late Sir William Jones is a most competent authority in all which relates to the poetry and music of the East, especially of Persia; and the following short quotation from him will show that the nightingales of Persia are equally disposed to imitate or contend with choice music, as the nightingales of countries farther to the west. "An intelligent Persian," says Sir William, in his Dissertation on the Musical Modes of the Hindûs, "declared he had been more than once present, when a celebrated lutanist, surnamed *Bul bul* (the nightingale), was playing to a large company in a grove near Schiraz, where he distinctly saw the nightingales trying to vie with the musician; sometimes warbling on trees, sometimes fluttering from branch to branch, as if they wished to approach the instrument, and at length dropping on the ground in a kind of ecstasy, from which they were soon raised, he assured me, by a change in the mode." It would be easy to fill volumes with well authenticated anecdotes, and impassioned descriptions of this charming songster; but the above must suffice for our purpose.

THE GREATER NIGHTINGALE. (*M. Luscinia major*, Linnaeus; *C. Philomela*). The above description applies chiefly or exclusively to the common nightingale of the species which visits England and the west of Europe; but there is, in the eastern parts of central Europe, one which has been considered as a different species, and that for the reasons following: it is larger than the other, being an inch longer in the body, half an inch longer in the tail, having a larger head and stronger bill, and different in its colours and its song. In this one the upper part of the body is dusky brownish-grey, the white on the throat has a

NAT. HIST.—VOL. III.

dusky black border, the breast is brown mottled with darker, the belly is dull white, and the wings and tail are deeper brown than those of the common nightingale.

Altogether this seems a stronger and more vigorous bird than the common nightingale; and the notes of its song are so loud that it can hardly be tolerated in an apartment, except by those who are passionately fond of birds. Altogether its song is far inferior to that of the other, notwithstanding its ear-piercing loudness; and it is liable to break off and jar, and not bring its melodies to those fine trills and cadences which are so pleasant in the song of the common nightingale. There is no particular mention of this one in the south of Europe or the East; and Austria and Poland seem to be the countries in which it is most abundant, though Hungary on the east, Bohemia on the west, and partially also some parts of Saxony, are included within its range. It is most plentiful near the banks of the rivers in Hungary, and those of the Vistula in Poland. It is said to be more numerous there than the common nightingale, though its song is inferior to what it is farther south. No mention is made of the occurrence of this bird on the north side of the Baltic, it has not occurred in Britain even as a straggler we believe; and we are not aware of its having occurred even in France. It thus seems peculiar to a certain longitude in Europe, and is probably not so migratory in latitude as the common species; but of its manners, if they differ from the manners of the other, nothing is known with certainty. The difference in appearance between them seems of itself scarcely sufficient to constitute a specific difference; and as for the difference of song, one would require to hear the two birds before absolutely deciding between them. In order to enable the curious among our readers to do this, we shall quote the literal translations of the two as given by Bechstein, who, as he endeavoured to make a sort of language for them, is perhaps to be preferred to those who have measured their powers by the gamut of music. The song of the common nightingale, says Bechstein, "is so articulate, so speaking, that it may be very well written," (of course he writes it well). "The following is a trial which I made on that of a nightingale in my neighbourhood, which passes for a capital singer:—

Tion, tion, tion, tion.

NIGHTSHADE is the *Solanum dulcamara* of Linnæus, a common British weed found in hedges. It is also called bitter-sweet, or felon-wood ; its fruit, leaves, and stem being all poisonous. The *Atropa belladonna* is called the *deadly nightshade*.

NIPA (Rumphius). A genus of palms found in the East Indies. It requires, in our stoves, a loamy soil and strong moist heat.

NIPPLEWORT is the *Lapsana communis* of Linnæus, a common British weed, belonging to *Compositæ*.

NIRMIDÆ (Leach). A family of apterous insects belonging to the order *Anoplura*, and composed of the various species of lice found upon birds, to which they are exclusively attached, with the exception of one species found upon the dog. The mouth is placed on the under side of the head, and composed of two lips and two hooked mandibles ; the tarsi are distinct, and terminated by two equal-sized hooks ; the head is generally large and triangular, semicircular or crescent-shaped, and occasionally with angular projections. The sexes also differ in the size of the head and the antennæ. M. Savigny also observed a pair of maxillæ with a minute palpus, hidden by the lower lip, which has also a pair of palpi. The body is small and depressed, of an oval or elongated form, and often varied with spots of different colours. Some of the species are very peculiar in their forms. M. Leclerc de Laval informed Latreille that he had discovered in the stomach bits of bird's feathers, and hence he believed that this constituted their food. De Geer, however, found the stomach of one of the species filled with blood with which it had gorged itself. It is certain that they are able to live but a short time upon dead birds, upon which they may be seen crawling with an evident desire of escaping. The family has found but few authors who have taken any interest in its investigation. Redi, however, long since figured many species in a rude manner ; and more recently we find, in the posthumous work of Lyonnet, representations of many others. Dr. Nitzsch also has published an elaborate monograph in the Magazine d'Entomologie of Germar ; and S. G. Children, Esq., S.R., has just published descriptions of some of the arctic species brought home by Captain Back.

NISSOLIA (Jacquin). A genus of evergreen shrubs and climbers, natives of South America ; the flowers are diadelphous, and belong to *Leguminosæ*. The plants succeed potted in sandy loam, and may be increased by cuttings.

NITIDULIDÆ (Leach). A family of coleopterous insects belonging to the section *Pentamera* and sub-section *Cercophaga*, having the body small and generally shield-shaped, with lateral margins ; the mandibles are notched at the tips ; the basal joint of the tarsi often small ; the club of the antennæ perfoliate, two or three-jointed, and short ; the palpi short, filiform, or but slightly thickened at the tips ; the legs moderately long, and the tarsi pilose. These insects are of small size, and frequent decaying animal or vegetable matter, some species being found in rotten bones, others in the damp matter which exudes from the wounds of trees, others again in boleti and fungi, and some under the bark of trees. This family is nearly allied to the *Silphidæ*, or carrion beetles, the connection being satisfactorily established by the genera *Peldis* and *Thymalus*. Some of the smaller species frequent flowers, and these are of a metallic colour ; the others are of obscure hues, but are often varied with spots or markings. The family comprises the following genera:—*Thymalus*, *Nitidulæ*, *Strongylus*, *Campa*, *Meligethes*, *Pria*, *Carpophilus*, *Anisocerus*, *Cateretes*, and *Mecropeplus*, all of which are British. The typical genus, *Nitidula* (Fabricius), is distinguished by the sub-depressed form ; elytra rounded behind ; sides of the thorax not depressed ; and the third joint of the antennæ larger than the fourth. There are about twenty-five British species, including *N. depressa* (*Silpha depressa*, Linnæus), which is of a brown colour, with black spots. It is rather less than one-sixth of an inch long, and frequents the bark of willow trees.

NITRARIA (Linnæus). A genus of deciduous shrubs found in the north of Asia, belonging to *Ficoideæ*. The species thrive in sandy loam, and may be increased by cuttings. According to Sweet, the soil should be impregnated with a little salt to assist the growth, as they are maritime plants.

NIVENIA (Dr. R. Brown). A fine genus of Cape plants, belonging to the fourth class of Linnæus, and to the natural order *Proteaceæ*. Generic character: involucre of four leaves, four-flowered, fruit hard ; receptacle smooth and naked ; calyx in four equal deciduous divisions ; scales round the germen free ; stigma clubbed and erect, nut swollen, sitting, and entire at the base. These plants thrive in a compost of loam, sand, and moor-earth, and require careful draining, and to be kept in a dry airy part of the greenhouse. They are propagated by cuttings, but not in heat.

NOCCA (Cavanille). Mexican shrubs belonging to *Compositæ*, formerly the *Lagascus* of Kunth. They do well in the greenhouse.

NOCTUIDÆ (Stephens; *NOCTUELITES*, Latreille). A very extensive family of lepidopterous insects, belonging to the section *Nocturna*, and distinguished by the elongated spiral tongue ; the palpi sub-compressed, terminated by a small joint ; the wings of moderate length, the anterior being subtriangular, and not convoluted when at rest ; the body thick, and covered with scales ; the antennæ generally simple ; the thorax often crested ; the abdomen conical ; the nerves of the wings are very strong, and the flight of the insects very rapid. "The typical groups of the *Noctuidæ*," observes Mr. Stephens, "as their name imports, fly only by night, and repose during the day on the crevices of the bark of trees, old walls, palings, &c., though others not only fly by night, but during the afternoon and at twilight." The

position of the wings during repose varies much; in some groups (as *Triphaena*, &c.) they are placed horizontally, and closely applied to the body, giving the insect a somewhat cylindrical form; in others (*Catocala*, &c.) they are also placed horizontally, but somewhat expanded, and forming a triangle; in others (as *Phisia*) they are considerably deflexed, and the thorax is crested; there is also considerable diversity in the form of the wings, though in general the anterior ones are elongate-triangular, and the posterior somewhat triangular-orbicular; some few have the posterior margins denticulated; and the anterior wings are mostly ornamented with two stigmata, one more or less circular, the other reniform (kidney-shaped), a character rarely observed in any other family of this order. The larvæ are usually solitary, do not reside in a web, neither are they subcutaneous; but those of the genus *Ceropacha* twist up the leaves similarly to those of the *Tortricidæ*; the pupæ are usually subterranean. The caterpillars have generally sixteen feet; some, however, have only fourteen or twelve; the posterior or anal pair are never absent; and in those species which have only twelve the anterior pair of the prolegs is as large as the following pair.

This family corresponds with the Linnæan section *Phalæna Noctua*, and comprises nearly four hundred British species, being mostly of a large or moderate size, and intermediate, as it were, between the *Bombycidæ* and the *Pyrælidæ* or *Tortricidæ*. These are divided by Mr. Stephens into about eighty genera, often resting upon minute structural differences, which renders it unnecessary for us to notice them in detail, or even to give a list of them. In the work of Ochsenheimer upon the European Lepidoptera this family comprises forty-two genera, corresponding for the most part with the sections proposed in a valuable work published many years ago, containing a classification of the lepidoptera found near Vienna, and in which great use was made of the characters obtained from the transformations of these insects, and which consequently afford good distinctive groups. The classification of this family is certainly a matter of difficulty, which is greatly increased by the exotic species having been almost entirely neglected, lepidopterists having chiefly confined themselves to the European species, although it is evident, from the figures of many insects given by Drury, Cramer, &c., that the extra-European species exhibit even greater diversity of form than those of Europe. Dr. Horsfield proposes to divide the family into three principal groups upon the consideration of their metamorphoses; and Latreille, after separating the genus *Erebus* (in which the wings are always extended and horizontal, and the last joint of the palpi long and naked, and which comprises some of the most gigantic exotic species of the order), proposes to divide the remainder into two extensive and parallel series. In the first the larvæ are geometrical, having either sixteen or twelve feet; and in the second the larvæ are sixteen-legged. *Erastria* and *Chrysoptera* appear to terminate the respective series, and respectively to tend towards the *Pyrælidæ*. Amongst the British genera may be especially mentioned *Catocala*, *Cucullia*, *Triphaena*, *Agrotis*, *Manestra*, *Calyptra* (the herald moth, *C. libatrix*), *Xanthia* (the swallow moths), *Leucanæa* (the wainscot moths), *Phæsea* (the spangled moths), and *Mormo* (the old-lady moth), descriptions of most of which will be found in their alphabetical

places. It is to be regretted, amidst the introduction of these new generic groups, that the old name *Noctua* appears to have been lost sight of as a generic title.

NOCTURNA (Latreille). A section of lepidopterous insects which fly by night. See **LEPIDOPTERA**.

NODOSARIA (Lamarck; **NAUTILUS**, Linnæus). A genus of molluscs of the family *Orthocerata*, a very confused and badly arranged genus, which under the title *Orthoceras* includes many recent and fossil species, many of the latter being probably no other than the spines of *Echini*, and many have been described as minute *Nautili*. The recent species are found, some of them, on the Mediterranean shores, buried in the sands. This genus, like that of the *Spirula* of Linnæus, is blended with his genus *Nautilus*.

NOLANA (Linnæus). A genus of South American annuals, introduced into our flower gardens about 1761. They belong to *Solanææ*, and are pretty flowering creepers.

NOLITANGERE is the *Impatiens nolitangere* of Linnæus, an English annual, remarkable for the elastic power of its capsules, which, when touched, discharge the seeds with considerable force.

NOMADA (Fabricius). A genus of bees, belonging to the family *Apidæ* and subfamily *Cuckoo-bees* (*Cuculinæ*, which see), having three sub-marginal cells and six joints in the maxillary palpi; the labrum is short and suboval. This is an extensive genus, consisting of nearly forty British species, being of a slender form, with the body destitute of pubescence, and ornamented with red and yellow or white bands, giving the insects the appearance of small wasps. They are chiefly found in the spring flying over sunny banks, and endeavouring to deposit their eggs in the provisioned nests of other bees, especially *Andrenæ*. The type of the genus is the *Apis ruficornis*, Linnæus.

NONATELIA (Aublet). A genus of South American evergreen shrubs, with pentandrous flowers, and belonging to the natural order *Rubiaceæ*. This genus has been called *Psychotria* by other authors.

NONEA (Moench). A genus of European annuals belonging to *Boraginææ*. This genus of plants was named *Lycopus* by Linnæus, but separated by Moench.

NORANTEA (Aublet). South American evergreen shrubs, bearing polyandrous flowers, and belonging to *Marcgraviaceæ*. They are stove plants, and succeed under the ordinary management.

NORWAY SPRUCE FIR is the *Abies excelsa* of Poiret, a well-known forest tree.

NOTARCHUS (Cuvier). This is a genus of molluscs without a testaceous covering. The animal's body is of a globular form, the foot similar to that of the *Bursatella*, to which it appears nearly allied, it has four tentacles, separated through a portion of their length, without prolonged labial appendages; a very small lateral superior branchia, nearly external, or merely protected by a small fold of the mantle; it has no internal testaceous portion. The only species described is the *N. Cuvieri*, which inhabits the Isle of France. This genus forms a connecting link between the *Bursatella* and the *Elysia*, and is one genus of the family *Aplysiaceæ*.

NOTELÆA (Ventenat). A genus of Australian evergreen shrubs, belonging to *Oleinææ*. The flowers are inconspicuous, but the plants are ornamental, and are managed like other plants from the same quarter.

NOTIOPHILUS (Duneri). A genus of coleo-

pterous insects belonging to the family *Carabidæ* and subfamily *Elaphridæ*, having the body depressed and elongate, the eyes large, the forehead channelled, and the elytra with a smooth and polished longitudinal space along each. These are very active little insects, found in gardens under stones, in sand, and gravel pots. They are generally of a shining copper or brassy colour. Entomologists are much at variance respecting the numbers of species which we possess in this genus. Stephens, in his *Illustrations*, gave two, suggesting the probability that we had more than that number. Mr. Waterhouse subsequently published a monograph in the *Entomological Magazine*, in which he described eighteen, which number Mr. Stephens has still more recently reduced to six, in the second edition of his *Nomenclature*. The type is the *Cicindela aquaticæ* of Linnæus, which is nearly a quarter of an inch in length.

NOTODONTIDÆ (Stephens). A family, or perhaps rather a subfamily, of lepidopterous insects, separated from the Linnæan division *BOMBYX* (which see), characterised by the possession of a very short distinct but not spiral tongue, the antennæ bipectinated, especially in the males, the body more or less robust, and terminated by a tuft in the males. The larvæ generally fleshy and naked, or slightly hairy, with one or more tubercles, mostly with sixteen legs, the anal pair of which are in some species (the puss and kitten moths, *Cerura*) converted into a porrected caudal appendage; the pupa enclosed in a cocoon, and often buried in the earth. This family is perhaps too nearly allied to the *Archidæ*, with which it is indeed united by Latreille, composing his third section of *Nocturna*, named *Pseudo bombyces*. It comprises, according to Stephens, fourteen genera, including *Pygæra* (*P. bucephala*, the buff-tip moth), *Cerura*, *Stauropus* (*S. Fagi*, the lobster-moth), *Endromis* (*E. versicolor*, the glory of Kent moth), and *Notodonta* of Ochseneimer, so named from the tooth or elevated scale upon the posterior edge of the anterior wings, and which, when the wings are closed, meet and form a crest on the back; hence the English name of the prominent moths given to these insects. Mr. Stephens has restricted this genus to the *N. dromedarius* (small crow prominent), *perfuscus* (dark prominent), and *ziczac* (pebble prominent). The swallow prominent (*dictæa* and *dictæoides*) form the genus *Lecocampa*, Stephens; the coxcomb and maple prominents the genus *Lophopteryx*, Stephens; and the pale prominent (*palpina*) the genus *Pterostoma*, Germar (*Ptilodontis*, Stephens; *Orthorhinia*, Boisduval; *Odoriptera*, Latreille). They are all handsome moths, and many of them of considerable variety.

NOTONECTIDÆ (Leach). A family of aquatic hemipterous insects, belonging to the section *Hydrocoriæ*, Latreille, differing from the *Nepidæ* in the fore legs not being raptorial, but simple, directed downwards, with the thighs of the ordinary size and the tarsi similar to those of the hind feet, and very much ciliated or clothed with lateral hairs; the body is thick and of an oval or sub-cylindrical form, and much less depressed than in the *Nepidæ*; the hind legs are admirably adapted, both in their structure and mode of insertion, for swimming, being fringed with strong hairs and terminated with two very minute tongues. With the assistance of these legs, they swim with great rapidity. The name of the family is derived from the peculiar habit which these insects have of swimming with the back downwards. On approach-

ing a piece of standing water, these insects may be seen resting with the tail upwards touching the surface, and the legs extending at nearly right angles from the body. In this position they are enabled to obtain a supply of air to the apertures of the air tubes along the sides of the body in the same manner as the *Dyticidæ*. No sooner, however, do they gain information of our approach (and how this is effected so quickly by insects whose heads are half an inch under water with the tail uppermost it is difficult to conceive) than they strike downwards, and are out of sight in an instant. They reside in the water in all their states, but the imago sometimes quits its native element and takes flight. The larva differs only from the imago in wanting wings and hemelytra. They are predaceous, feeding upon other insects which they seize with their short fore legs, and convey it to the proboscis. They are very bold, and will attack insects larger than themselves, and even their own species; they also destroy considerable numbers of the larvæ of the *Ephemera* which are themselves predaceous. They are enabled to produce a smart wound with their proboscis. The female deposits a considerable number of white elongated eggs, which it attaches to the stalks of aquatic plants. In the commencement of the following spring, these eggs hatch and produce minute active and voracious larvæ which afterwards become pupæ, differing from the former state in having rudiments of the organs of flight. The family is but of small extent and corresponds with the Linnæan genus *Notonecta*; it now comprises the genera *Notonecta*, *Ploa*, *Sigara*, and *Corixia*. The genus *Notonecta* is distinguished by its sub-cylindrical form, the scutellum large and distinct, with the first joint of the anterior tarsi long, and the claws of the hind legs minute. There are three British species, the type being the *N. glauca* of Linnæus, about half an inch long, of a greyish colour, with the margins of the elytra spotted with small black dots, and the back of the abdomen black. Dr. Leach has published a good monograph upon this family, in the twelfth volume of the Linnæan Transactions.

NOTOXIDÆ (Stephens; *ANTHICIDÆ*, Latreille). A family of small coleopterous insects, belonging to the section *Heteromera*, and subsection *Trachelidæ*, Latreille, having the antennæ simple and slightly thickened towards the tips, the joints being of a reversed conical form, the maxillary palpi terminated by a large hatchet-shaped joint, the penultimate joint of the tarsi bilobed, the body narrowed in front, the neck generally distinct, the thorax narrowed behind or knotted. The species are of minute size, in general very active, often found in the neighbourhood of dung-heaps, or in sandy situations, others are found upon different plants. Latreille places in this family the genera *Scaptia*, *Steropes*, *Notorus*, and *Anthicus*, the typical genus being distinguished at once by a large horn produced from the front of the thorax and extending over the head. The type is the *Notorus monoceros* (Linnæus, *G. meloe*), a small and not very common species, which is prettily varied with brown and red, and found upon sand banks. The genus *Anthicus* comprises numerous small species, having the thorax unarmed.

NOTREMA. A genus of molluscs established by Rafinesque, neither the animal nor the shell is accurately known, and the only idea we can form of it is the *Hippomix* placed upon a distinct basis, with its

summit closed by a kind of operculum, analogous, perhaps, to the piece which closes the aperture of the *Fissurella*. So doubtful from the description we have of this genus is its proper place in malacology, that we are almost disposed to consider it a species of *Balanus*, hitherto but little examined.

NUCLEOBANCHIATA. The fifth order of De Blainville's malacology, second class, *Syphobanchiata*. It includes the first family *Nectopoda*, composed of the genera *Pterotrachia* and *Carinaria*; second family *Pteropoda*, composed of the genera *Atalanta*, *Spiratella*, and *Argonauta*. The distinguishing characteristics of this order are the animals possessing a wing-like appendage on each side of the body, serving as propelling organs; the body gelatinous. The shell symmetrical, more or less turned longitudinally forward, and the texture very thin. One species of this order, the *Argonauta*, has given rise to doubts, whether the animal found in it, is the "architect of its fairy bark" or not; and two thousand years have elapsed without that question being yet set at rest. The general opinion seems, however, to be, that the animal discovered in the *Argonauta* is only a pirate, and not its proper inhabitant.

NUCULA (Lamarck). This genus of molluscs appears to form an evident transition to the genus *Trigonia*, and is the last division Lamarck has made of the genus *Arca*, of Linnæus, from which and the two other divisions it differs, in consequence of the ligament being partially inserted internally without the angular groove in the exterior of the valves, these are more or less pearly within, as are also those of the *Trigonia*, and evidently indicate an alliance with the *Naiades*. Lamarck describes six living species, and four fossil; of the first, three inhabit the European seas, and the rest the eastern ocean. De Blainville places this genus following the *Petunculus*, and it is the last of the family *Polyodonta*, or *Arks*.

NUMMULACEA is De Blainville's third family of the second order *Cellulacea*, and contains the genera *Nummulites*, *Helicites*, *Siderolites*, *Orbiculina*, *Placentalia*, and *Vorticialis*. Of the genus *Siderolites*, two recent species are known; of the *Orbiculina* three; of the *Placentalia* two; of the *Vorticialis* four species of a microscopic size; the rest are fossils analogous to this family.

NUMMULITES. A genus of fossil molluscs. De France enumerates about twenty, but more are known; the animal is of course entirely unknown; but the form of its habitation is lenticular, not exhibiting any appearance of the whorls of the spire, which are altogether interior, and divided into a great number of small cells separated by a partition, which is not perforated by a syphon.

NUPHAR (Smith). A genus of aquatic plants separated from the genus *Nymphaea*. The flowers are polyandrous, and belong to the natural order *Nymphaeaceae*. These are natives of northern climates, two of them are British, and frequently met with in brooks and pools. In Sweden, in years of scarcity, the roots of *Nuphar lutea* are pounded into cakes.

NUTCRACKER (*Nucifraga caryocatactes*). A genus of carnivorous birds, of the great order *Passeres*, and as such ranging with the crow family. Only one species is known as strictly belonging to this genus, the common nutcracker, or European bird, but so rare in Britain as to merit the character of only an occasional straggler. Generically it may be thus described: the bill large, long, straight, arched

in the culmen, compressed laterally, and margined and pointed at the tip. The upper mandible rounded in its section, without any prominent ridge, and exceeding the lower mandible in length. The nostrils, at the base of the bill, small, open, but shaded by bristly feathers directed forwards; four toes to the feet, three in front and one in the rear, the external front one united to the middle at the base; and the tarsus longer than the middle toe. The wings wedge-shaped, the first and sixth quills being equal, and the fourth the longest in the wing.

The size and markings of the species are as follow: The length about thirteen inches, of which the tail occupies rather more than four; and the bird is thus about the size of the magpie. The general plumage of the male is black, with a decided brownish tinge, and mottled over with small white spots, very similar to those on the starling upon all parts, except the top of the head; these spots are most numerous on the under parts, where they form irregular clusters. The tail feathers are also marked with a large white bar at the ends; the bill and the feet are greyish, and the irides brown. The female is brighter brown than the male, and has something of a reddish cast. The colours are, however, by no means constant, either in different individuals or in the same individuals at different ages and seasons. Individuals are not unfrequently met with of a sort of albino character, the ground colour being the same dull white as the spots upon the ones commonly met with, and the spots being pure white. These birds belong to the northern hemisphere, and are not uncommon in the cold regions; and they rarely quit the fastnesses of their favourite mountains and woods, unless when driven thence by the severity of the weather. In Europe they extend from Lapland to the foot of the Alps; but they are to be considered more in the light of resident birds upon those localities which they prefer than as regular migrants with the seasons. They are very voracious and indiscriminate in their food, which consists both of the seeds and kernels of trees, and of various insects and their larvæ; they are partial to pine forests, where they hew the seeds out of the cones with their powerful bills; but they also feed upon acorns, nuts, and beech-mast, the coverings of which they break open with the greatest care. At some seasons they tap the bark of trees something after the same manner of woodpeckers; but they do not punch into the wood, or capture insects with the tongue, in the same manner as those curious creatures. During summer the nutcrackers inhabit the depths of the woods, and are said to be partial to those places of them near which there are springs and rills of water; but in severe snow storms, and indeed during the winter generally, they approach the abodes of mankind, and, like most omnivorous birds, pick up such substances as they can find, whether animal or vegetable. The nest is usually placed in the hole of a tree, and the birds are said to trim and enlarge those holes in the same manner as is done by woodpeckers. Indeed the nutcrackers seem to combine, to a considerable extent, the habits of the woodpeckers and those of the other omnivorous birds. Nutcrackers have nothing which can be called a song, for theirs is not a musical family. Most of the genera can, however, be taught to articulate words, and it is probable that the nutcrackers have this property, though we are not aware that it has been tried.

NUTHATCH (*Sitta*). A genus of *Tenuirostral*

birds with *anisodactylic* feet, of which the characters are : the bill of mean length, straight, circular in its section, depressed, conical toward the point, where the cutting edges are particularly sharp, and the texture very firm. The nostrils are placed at the base of the bill, rounded, and covered by bristly feathers. Four toes on each foot, the external one united to the middle of the base, and the hind one large and armed with a strong claw. There are twelve feathers in the tail, nearly square over at the ends, and with flexible shafts. The first quill of the wing very short, the second also shorter than the third, and the fourth is the longest in the wing. These birds are excellent climbers, and in this respect have no inconsiderable resemblance to the woodpeckers, and also to the tits, the former of which they resemble in their action upon the stems and large branches of trees, and the latter, in their action upon the small branches, from which they can hang suspended in a variety of positions ; and thus search every part of a tree from the bottom of the trunk to the remotest bud, for insects or for nuts and seeds, all of which indiscriminately form part of their food according to the season.

The typical species is the common nuthatch (*Sitta Europæa*). It is about six inches in length, with a bill three quarters of an inch long, slender, but firm in its texture, and stiff by both mandibles being curved ; the upper mandible is blackish-blue, the lower one paler, and yellow at the base. The feet are yellowish-grey, furnished with very strong claws. The male bird is bluish-grey on the upper part, and blue on the forehead ; the cheeks and throat are white, shown off by a black streak which extends from the gape to the neck ; the flanks and thighs are brownish, and the breast and belly dull yellow. The quills are blackish, and the tail-feathers, which are twelve in number, are bluish-grey, except the lateral ones, which are black, and a white bar crosses the tail near the tip. As a British bird, the nuthatch is confined to the south of England, to nearly the same range as that occupied by the woodpecker ; but it is a bird of different habits, not being migratory. It has not been observed in the extreme west of England, "We have never," says Montagu, "observed it far north, nor so far west as Cornwall. It chiefly affects wooded and enclosed situations, choosing the deserted habitation of a woodpecker in some tree for the place of nidification. This hole is first contracted by a plaster of clay, leaving only sufficient room for itself to pass in and out. The nest is then made of dead leaves, most times that of the oak, which are heaped together without much order. The eggs are six or seven in number, white, spotted with rust-colour, so exactly like those of the oxeye in size and markings, that it is impossible to distinguish any difference. If the barrier of plaster at the entrance is destroyed when they have eggs, it is speedily replaced ; a peculiar instinct to prevent their nest being destroyed by the woodpecker and other birds of superior size, which build in the same situation."

As these birds have no song, they are kept in confinement only for the sake of their manners, even in those countries where the people are most partial to confine birds. Anecdotes are told of the difference between their manners when they are a sort of partially tamed in a free state, and when they are forcibly confined. "A lady," says Bechstein, "amused herself in the winter, and particularly when the snow

was on the ground, with throwing, several times a day, different kinds of seeds on the terrace below the window, in order to feed the birds in the neighbourhood. These soon became accustomed to this distribution, and arrived in crowds when they heard the clapping of hands, which was the signal used to call them. She put some hempsced and cracked nuts even on the window-sill, and on a board, particularly for her favourites, the blue-tits. Two nuthatches came one day to have their share in this repast, and were so pleased, that they became quite familiar, and did not even go away in the following spring to get their natural food, and to build their nest in the wood. They settled themselves in the hollow of an old tree near the house ; as soon as the two young ones which they reared here were able to fly, they brought them to the hospitable window where they were to be nourished, and soon after disappeared entirely. It was very amusing to see these two new visitors hang or climb on the wall or blinds, whilst their benefactress put their food on the board. These pretty creatures, as well as the tits, knew her so well, that when she drove away the sparrows which came to steal what was not intended for them, they did not fly away also, but seemed to know that what was done was only to protect and defend them." The different habit of the bird in a state of involuntary confinement is shown in the following account. "A nuthatch, which had been accidentally winged by a sportsman, was kept in a small cage of plain oak-wood and wire. During a night and a day that his confinement lasted, his tapping labour was incessant ; and after occupying his prison for that short space, he left the wood-work pierced and worn like worm-eaten timber. His impatience at his situation was excessive ; his efforts to escape were unremitting, and displayed much intelligence and cunning. He was fierce, fearlessly familiar, and voracious of the food placed before him. At the close of the second day he sunk under the combined effects of his vexation, assiduity, and voracity. His hammering was peculiarly laborious, for he did not peck as other birds do, but grasping hold with his immense feet, he turned upon them as a pivot, and struck with the whole weight of his body, thus assuming the appearance, with his entire form, of the head of a hammer, or, as birds may be seen sometimes to do on mechanical clocks, made to strike the hour by swinging on a wheel."

The common nuthatch is the only one which is found in Europe, or any of the immediately adjacent parts of the world ; but there are some others in America and in the eastern Asiatic islands. These are all like the common species of tree birds, and remarkable for their expertness in climbing ; and their manners do not appear to differ greatly from those of European nuthatch.

THE CAROLINA NUTHATCH (*S. melanocephala*) is not an uncommon species in North America, though some have regarded it as only a variety of the European one. It differs, however, in many respects, and some very zealous and talented students of animals, Mr. E. Blyth among the rest, are of opinion that, how much soever European and American animals may resemble each other, they are still specifically different. We do not take upon us to decide this ; but we shall quote Wilson's account of the differences between the two, and also his finely characteristic account of the manners of the birds. "The head and

back of the European species," says Wilson, "are of a uniform bluish grey; the upper parts of the head, neck, and shoulders of ours are a deep black glossed with green; the breast and belly of the former are a dull orange, with streaks of chestnut; those parts in the latter are pure white. The European has a line of black passing through the eye, half way down the neck; the present species has nothing of the kind, but appears with the inner webs of the three shortest secondaries and primaries of a jet black; the latter tipped with white, and the vent and lower parts of the thighs of a rust colour. The European, therefore, and the present are evidently two distinct and different species. The bird builds its nest early in April, in the hole of a tree, in the hollow rail in a fence, and sometimes in the wooden cornices under the eaves, and lays five eggs of a dull white, spotted with brown at the greater end. The male is extremely attentive to the female while sitting, supplying her regularly with sustenance, stopping frequently at the mouth of the hole, calling and offering her what he has brought in the most endearing manner. Sometimes he seems to stop merely to inquire how she is, and to lighten the tedious moments with his soothing chatter. He seldom rambles far from the spot; and when danger appears, regardless of his own safety, he flies instantly to alarm her. When both are feeding on the trunk of the same tree, or of adjoining ones, he is perpetually calling on her; and, from the momentary pause he makes, it is plain that he feels pleased to hear her reply.

"The white-breasted nuthatch is common almost every where in the woods of North America, and may be known at a distance by the notes *quank, quank*, frequently repeated, as he moves upward and down in spiral circles around the body and larger branches of the trees, probing behind the thin scaly bark of the white oak, and shelling off considerable pieces of it, in his search after spiders, ants, insects, and their larvæ. He rests and roosts with his head downwards, and appears to possess a degree of curiosity not common in many birds, frequently descending very silently within a few feet of the root of the tree where you happen to stand, stooping, head downwards, stretching out his neck in a horizontal position, as if to reconnoitre your appearance; and, after several minutes' silent observation, wheeling round, he again mounts with fresh activity, piping his unisons as before. Strongly attached to his native forests, he seldom forsakes them; and, amidst the rigours of the severest winter weather, his note is still heard in the bleak leafless woods, and among the howling branches. Sometimes the rain, freezing as it falls, encloses every twig, and even the trunk of the tree, in a hard transparent coat or shell of ice. On these occasions I have heard his anxiety and dissatisfaction at being with difficulty able to make his way along the smooth surface; at these times generally abandoning the trees, gleaning about the stables, around the house, mixing among the fowls, entering the barn, and examining the beams and rafters, and every place where he may pick up a subsistence."

RED-BELLIED BLACK-CAPPED NUTHATCH (*S. varia*). This is a smaller species than the preceding. It measures only four and a half inches in length in the body, and the stretch of the wings is about eight inches. It corresponds exactly with the last in the form of the bill, nostrils, and tongue, and also in the colour of the back and tail feathers. The secondaries,

however, are not varied with so deep a black as the other species. The legs, feet, and claws, are of a dingy greenish yellow; the head is black on the upper part; a stripe of white encircles the frontlet; a streak of black passes through the eye, reaching to the shoulder; under this streak there is a line of white, and the chin is also of this latter colour. The wings and primaries are of dusky lead colour, and the other under parts are light russet. The top of the head of the female is not of so deep a black as the male, nor is the belly and breast of so intense a brown.

These birds are migratory. They breed in the northern states, whence they pass to the southern ones in October, and return in April. This and the last mentioned species are readily distinguished both by the smallness of its size and the superior swiftness of its motions. There is also a decided difference in the voices of the two species. The notes of the present one are much sharper and quicker, and nearly an octave higher; but there is not much difference in the music they produce, which is altogether a monotonous and untuneful stave. From the close resemblance they bear in point of colours and general habits, it is not unlikely that in their mode of constructing their nests, and in other parts of their economy, they may also make a similar approach to each other. Both these little birds are extremely useful, on account of their destroying vast quantities of those destructive insects and their larvæ which are so destructive to our fruit and forest trees. Their principal haunts are those forests where pines are most abundant, especially in the winter season, as the seeds of the pine seems to be their favourite food.

It is highly probable that this migratory species has been called by different names in different parts of America, and different states of its plumage, though we still want correct information respecting the birds of those parts of the United States to which the keen-eyed observation of Wilson did not extend. According to him, and within the limits of his observation, the pine forests are almost the exclusive haunts of the red-bellied and black capped nuthatches; and many thousand acres of the deciduous forests may be traversed in winter without finding them, though they are abundant on the pine barrens as they are styled in that part of the country. It is indeed a point worth attending to in the natural history of pine forests, that the birds which take up their habitation almost exclusively there, are nearly as permanent all the year round in the locality as the greenness of the leaves. We find it so in the peculiar birds of the pine forests of Europe, however small they may be, and apparently ill able to endure the severe winters of the north; for the little crested wrens remain secure in the cover of the pines, when much larger birds, which summer on the open grounds in the same regions, are driven southward in flocks. In those pine forests, the red-bellied nuthatches are most frequently found in pairs, and not in flocks or packs of their own species, though they associate readily with tits, small-spotted woodpeckers, and other birds which prefer similar localities, and are capable of similar activity. "The whole tribe" (meaning the black-capped tit, the crested tit, the little spotted woodpecker, and these nuthatches), says Wilson, "proceed regularly from tree to tree through the woods like a corps of pioneers; while, in a calm day, the rattling of their bills, and the rapid motions of their bodies, thrown, like as many tumblers and rope-

dancers into numberless positions, together with the peculiar chattering of each, are altogether very amusing; conveying the idea of hungry diligence, bustle, and activity."

THE BROWN-HEADED NUTHATCH (*S. pusilla*) is another American species, resembling the last-mentioned one in its manners, but differing in its locality, its colours, and being a little smaller. It is about four inches and a quarter long, and not eight inches in the stretch of the wings. The upper part of the head and neck are light rusty-brown, except a white spot near the setting on of the neck. The brown is mottled with darker spots of the same, and there is a dusky streak across the nostril to the eye. The chin and sides of the neck under the eyes are white; the wings are dusky, with some of the secondary quills and coverts slate-colour, which last is the colour of the upper part of the two middle feathers of the tail, and of the tips of the other tail feathers; but there is a white bar across all the tail feathers near their tips, and within this bar all across the two middle ones are black. The legs and feet are dull blue; the bill is black, but blue toward the base of the lower mandible, and the irides are hazel. The female has the head darker brown, and the dark streak across the eye less conspicuous. The voice of this bird is also more shrill than that of the red-bellied one, and it is more social, being found in small flocks during the winter. It is an exceedingly active and vigilant little bird, moving in all directions, and upon the most slender twigs of the trees with great activity, so that there are very few of the smaller birds of North America, of which it is more difficult to obtain specimens. It is not understood to reach Canada, or the northern, or indeed the central states of the American Union.

Nuthatches are also mentioned as occurring in Jamaica and some others of the American islands, and parts of continental America farther to the south; but the accounts of these are by no means precise, and it is possible that they may be the same as some of the North American species. There are specific differences between all of these and the nuthatch of Europe; but as the habits and habitations are so nearly the same, it is probable that they may be subject to the same changes of colour as we have noticed in the European one; and, therefore, a new species must not be hastily founded on a single specimen. From the general habits of the birds, however, which are not migratory at all in some of the species, and but very slightly so in others, it is scarcely to be supposed that they could pass even as stragglers from the United States to the West India islands. We are, however, very much in want of correct information relative to the geographical arrangement of the forest birds of America, which are certainly more different from each other in different latitudes, than the birds of the eastern continent. The division between North and South America, in a natural point of view, is also greater than in the eastern continent; and as those tenants of the pine forests do not inhabit at very great elevations in their native localities, we are not to suppose that they would gain those heights in Mexico, on which alone pines are to be met with in that country; while, as they avoid the forests of deciduous trees in the north, it is not likely that they would follow the line of the coast of the Caribbean Sea.

VIOLEACEOUS NUTHATCH (*S. frontalis*).—This is a

more beautifully coloured bird than the European or any of the American species. The upper parts, including the head and nape, are rich azure; the sides of the neck and cheeks purplish-blue, and a distinct black band across the forehead (from which the specific name is given), and a smaller one of the same colour along each eye. The quill and tail feathers are blue, clouded with ash-colour; the chin white; the rest of the under part pale ash, clouded with purple; the naked parts of the feet brown; and the bill yellow in the greater part of its length, but black at the tip. This species measures about five inches in length; it is found in the forests of Sumatra, Java, and various other of the eastern islands. Its manners are little known; but it is highly probable that they differ considerably from those of the species which inhabit the pine forests of the north; nor is it at all unlikely, that if it were possible to examine those forests with the attention which its importance deserves, other species of these as well as tree birds of different genera would be found in them.

Some specimens of this genus have been brought from New Holland, which are still different from any of those hitherto described. One in particular has the colours of the last-named one reversed, being ash-coloured above and bright blue on the under part, and having the wings margined with golden yellow. Specimens have also been brought from Southern Africa, still different from these; but we have no account of their manners in that part of the world; and specimens imported from the Cape are not always natives of that country.

NUTMEG is the fruit, or rather the seed, of the *Myristica officinalis* of Linnæus, a well-known and valuable spice.

NUTTALLIA (Dickson). A genus of carrot-rooted herbs, natives of North America, belonging to the natural order *Malvaceæ*. They are cultivated in light rich soil, and, being almost hardy, succeed in our flower gardens with a slight defence against heavy rains and frost. They sometimes ripen seeds by which they may be increased.

NUT TREE is the *Corylus avellana* of Linnæus, a well-known British hedge plant, of which there are several varieties, as the filbert, cob-nut, &c.

NUT WEEVIL. The larva of this insect is the grub which is found in nuts. See *BALANTINUS*.

NYCTAGINEÆ. A natural order of plants comprising seven genera and forty-seven species. *Mirabilis*, the marvel of Peru, with *Abronia*, and the other associated genera, are herbaceous, shrubby, or arborescent plants, with occasionally tuberous under-ground stems and knotted stalks. Their leaves are exstipulate, opposite, rarely alternate, and almost always unequal. The inflorescence is axillary or terminal, the flowers solitary or aggregate, and surrounded by a calyx-like involucre of one or more leaves, one or more flowered, and persistent. The perianth is single, corollaceous, monophyllous, and tubular; the tube contracted above the germen, and persistent; the limb plaited in æstivation, twisted to the left, and deciduous; the stamens are free, and exserted from an annular disk; the filaments are attached to the tube of the perianth; the anthers are two-celled and burst lengthways; the germen is superior and free; the style is single and terminal; and the stigma capitate. The fruit is a thin membranaceous utricle, one seeded, and included within the indurated tube of the perianth.

The roots of the *Nyctagines* contain a purgative principle, which renders them useful as cathartics; one of them was formerly thought to afford the jalap of medicine, and was hence named *Mirabilis jalapa*, and, although not the true jalap, its roots are not unfrequently powdered and mixed with the genuine drug.

The *Abronia*s are extremely delicate and beautiful plants, but of no known use. The *Pisonia*s are remarkable for being shrubs and trees in a large group of herbaceous genera. *Pisonia aculeata*, which is a scrambling tree devoid of beauty, with reclining thorny branches, is very troublesome to travellers in the savannahs of the West Indian isles, by arresting those who endeavour to pass, its strong incurved spines fastening themselves to the clothes and almost forbidding transit. The order contains the following genera, viz., *Oxybaphus*, *Mirabilis*, *Abronia*, *Allionia*, *Boerhaavia*, *Pisonia*, and *Boldoa*, all noticed under their generic titles.

NYCTERESITION (Ruiz and Pavon). A South American fruit tree, having pentandrous flowers, and belonging to the natural order *Sapotææ*. This tree was called *Chrysophyllum splendens* by Sprengel.

NYCTERIBIA (Latreille). A small but extraordinary genus of wingless insects, very nearly allied to the *Hippoboscideæ*, or forest flies, and exclusively parasitic upon bats. The head is dorsal, very small, and generally bent backwards, and received in a channel which extends nearly to the base of the abdomen; the legs are very long; the basal joint of the tarsi as long as the tibiae; the base of the middle legs is furnished with a curious comb-like appendage, which is the analogue of the anterior wings; the head is furnished with signs of variable form, two antennæ, and a proboscis. The type of this genus is the *Pediculus vespertilionis*, Linnaeus. The motions of these insects are exceedingly quick; and, from the curious position of the head and the direction of the legs, which appear to be dorsal rather than ventral appendages, the movements are very curious. "It transports itself," says Mr. Montagu, "with such celerity from one part of the animal it inhabits to the opposite and most distant, although obstructed by the extreme thickness of the fur, that it is not readily taken. When two or three were put into a small phial, their agility appeared inconceivably great, for as their feet are incapable of fixing upon so smooth a body, their whole exertion was employed in laying hold of each other; and, in this most curious struggle, they appeared actually flying in circles; and when the bottle was reclined, they would frequently pass from one end to the other with astonishing velocity, accompanied by the same gyrations; if, by accident, they escaped each other, they very soon became motionless, and as quickly were the whole put in motion again by the least touch of the bottle, or the movement of an individual."—Linn. Trans., vol. xi., p. 13. There are two British species, whereof figures have been given by Leach and Curtis. A memoir, containing a complete account of the anatomy of these insects, with numerous illustrations, has been published in the first volume of the Transactions of the Zoological Society of London, in which several new exotic species have been described, and the transformations of this genus proved to be similar to those of *Hippoboscæ*, thus confirming the affinity between those groups.

NYCTERIUM (Ventenat). A genus of South

American shrubs, belonging to the fifth class of sexual botany, and to the natural order *Solanææ*. Generic character: calyx in from five to ten parts; corolla somewhat rotate and plaited; anthers connivent, opening by a pore at the apex; berry from two to four celled. This genus has borne several names, and is generally known as a *Solanum*. One of the species, *N. amazonium*, bears very showy flowers, and is a favourite stove plant. They are propagated by cuttings.

NYCTICHELIDON—Night-swallow. A numerous genus, or rather group, of fissirostral birds, forming, along with the day-swallows, the whole of that family of the order *Passeres*. In respect of names, these birds have been very unfortunate from the earliest periods of natural history, and they remain so at the present day. The typical bird, which was for a long time the only one known, is very much in the habit of resorting to cool places, where cattle stand when annoyed by flies; and it stood accused, as early as the days of Aristotle, of sucking goats, although its bill is quite unfit for any kind of suction; and, instead of doing any harm to ruminating animals when thus attending them, it does them a good deal of service by ridding them of the flies which annoy them. Still the bird got the name of "goatsucker," which name has passed through many languages, has remained to the present time, and has been applied to a great many species which have been discovered in foreign countries. To change the name of a number of birds, of which there are good descriptions under that name, is always inconvenient, as tending to destroy the general usefulness of first-hand information. The French have accordingly adopted one of their popular names for it, and called it *Engoulevent*, which means "swallower of the wind." This is not more correct than the former, though, as the bird flies open-mouthed when feeding, and as its gape is very wide, a large current of air sets into its mouth, and comes out again at the sides, where it makes a peculiar booming or whirring sound, something like that of the old-fashioned wheels used in the hand-spinning of wool. It has got some of its common English names from this sound, such as the "wheel bird," the "churn owl," the "jar owl," and latterly "night-jar," all of which are unfit for scientific purposes, and inapplicable to the greater number of the genus. It has also been called the "dor-hawk," partly perhaps from the sound which it emits having some resemblance to that emitted by the dor-beetle, and partly also from the number of those beetles which it captures. It has also been called the "fern owl," from its proneness to hawk about fern brakes in quest of its prey; and, among other names, the French have called it the "flying toad."

This multiplicity of names is a matter of small consequence in itself; but it serves to show the interest which the bird has attracted; and it must be admitted that this, the typical bird, is not only a very curious creature, but the family or subfamily of which it is the type is one of the most curious in the list of birds. The members of it differ greatly from each other in numerous respects, and these differences are often in points so essential that a subdivision into at least two genera has become necessary, in order that the generic characters might be more easily expressed and more clear. There is still, however, too much resemblance between the members of these two genera for admitting the perfect separation of the

description of their more general characters, and their place in nature ; and hence it becomes necessary to make use of some distinct name at the head of this general description. That which we have taken is not wholly unobjectionable ; but as we intend not to apply it either to the genera or the species, but to leave them under their old names, it may be used without any danger of misleading, and we have no desire to load the vocabulary with any new name, though it is still necessary to make a few general remarks on so curious a group of birds.

The genera which compose the group are *Caprimulgus*, or the goat-sucker properly so called, and *Podargus*, which has escaped the infliction of any peculiarly inappropriate name, but of which the scientific term which we have given, by a slight alteration of the last part, indicates that the feet are more clear, or fit for walking, than those of the former genus.

This being understood, we may mention that the swallows which feed by daylight, of which an account will be found in the article *HIRUNDO*, together with the present group, make up a family, which are so distinct in their habits that they ought perhaps to stand as a distinct order, under some such a name as *Chelonidæ*, and they are so arranged by some ornithologists. They take up the natural system where the birds of prey leave it off, far more naturally than it is taken up by those birds which are usually ranged nearest the birds of prey in the systems. Like them, too, they admit of division into two sections—diurnal feeders, or the swallows, and nocturnal feeders, or the group now under consideration, and the present group stand in almost precisely the same relation to the owls as the swallows do to the hawks and other diurnal birds of prey. The more powerful predatory birds, both diurnal and nocturnal, subsist chiefly on warm-blooded animals ; but the last and feeblest species of both subsist, in part at least, upon insects ; and the two sections of the *Chelonidæ* take up the insectivorous feeding where the others leave it off, the day ones feeding almost exclusively on the wing, but the night ones, as is understood, in part at least upon the ground, where they nestle among the herbage, and do not resort to elevated nesting places like the swallows. The difference between the day preyers and the night ones, and the agreement of each in the two orders, extend even to the plumage, and to the apparent strength and powers of endurance of the birds. The feathering of the swallows is firm and compact, like the feathering of hawks, while the birds of the present section have light bodies in proportion to their apparent size, and soft loose plumage like the owls. The lengths of their flights also correspond ; for, while the best-winged hawks do not surpass the high feeding swallows in rapidity or continuance of flight, the flight of the present section, so far as is known, is short, like that of the owls. There is therefore a distinct office in nature for all the chelonian birds, and there is a distinct time and manner for the labours of each division of them. They have not been sufficiently studied for enabling us to bring the details into a very systematic form, as interwoven with this general notice ; and so must take the rest that we have to say in the order of the two genera.

CAPRIMULGUS. The most striking characters of this genus are : a plumage of light texture, mottled and clouded with grey and brown, as is the case with most nocturnal birds. Their eyes are large, their bills are more deeply cleft than those of the swallows,

and they are furnished at the margins with stiff moustaches, while the birds can retain in the mouth, by means of their glutinous saliva, the largest insects which are on the wing at the time of their feeding. Their nostrils are at the base of the bill, drawn out in the form of little tubes. Their wings are very long, but their feet are short, have the tarsi feathered, the toes joined by short membranes at the bases ; and the hind toe partially united to the inner front one, and inclined a little forwards. The claw on the middle toe is often toothed like a sort of comb on its inner edge, and the outer front toe has only four phalanges.

They are birds, generally speaking, of retiring habits, rarely appearing during the day, and never in flocks. Their feeding time is in the twilight of still evenings, and their food is chiefly those moths, beetles, and other insects which are then on the wing. It is probable, however, that in still gloomy weather, they beat the bushes near the ground during the day ; and also that those which frequent the deep and twilight forests of tropical countries, find sufficient twilight in the shade of these for enabling them to seek their food, while most living creatures are driven to repose by the heat of a vertical sun, which, as it throws the shadow of the forest upon the ground immediately under it, makes the under sides of all the leaves and branches dark.

Those with which we are sufficiently acquainted to judge of their habits are not nocturnal but twilight ; and, indeed, the number of birds that are actually nocturnal is, in all probability, very few. Their long wings enable those birds to fly very lightly, so that being incessantly on the wing during their short feeding time does not greatly fatigue them. So far as is known too, they do not give themselves much trouble in preparing accommodation for their young, for their nests hardly deserve the name. The young also are few in a hatch ; and thus the finding of food for them is the less laborious. Still it is probable that the few which they have require more food in proportion to their numbers than the young of day birds, upon the well-known principle that the production of feathers is more expensive in this way than the production of bones and flesh. We do not know directly the quantity of food which any of the *caprimulgi* may carry to their young ; but as the analogy between them and the owls is very palpable in many other respects, we may naturally conclude that it must hold in the feeding also ; and we do know, from direct observation, that young owls consume an immense quantity of food, far more than any one would imagine, judging only from the trifling volume of their bodies.

Altogether the *caprimulgi* are most singular creatures ; and though there is but one of them which can be observed in a state of nature in Britain, and that one is somewhat local, and no where very numerous, yet their history is far from being the least inviting portion of ornithology. We shall now notice the leading species ; but with the exception of the one which is native in Britain, we shall be able to give little else than a mere catalogue.

EUROPEAN GOATSUCKER (*C. Europæus*). Being the only species, not of this genus merely, but of the whole family of night birds which prey upon insects on the wing, and being besides a remarkable bird both in its appearance and its manners, this bird has always excited a good deal of interest both among

the country people and the lovers of natural history. This has got it a great number of names, none of them very appropriate, and yet all of them much more accurate than goatsucker, which has been adopted by writers, because each of them applies to at least one character or habit of the bird, whereas this applies to no part of its character. It is called "dor-hawk," which is correct in so far as dor is concerned, because the dor-beetle, which flies and drones in the twilight, is a very favourite prey with it; but then it can with no propriety be called a hawk. It is also called the fern-owl, which is right again in as far as the fern is concerned; for the undersides of fronds of ferns are favourite haunts for the beetles and larger moths, upon which also this bird lays heavy contributions; but the bird is certainly not an owl either in appearance or habits. None of the owls, at least none of them which are found in any part of the British islands, prey on the wing; and this bird rarely, if ever, preys in any other manner. Its other provincial names are mostly given to it from the sounds which it utters. Those of course depend much upon the fancy of the parties imposing the names; and all such nomenclature puts one forcibly in mind of the proverb,

As the fool thinks, so the bell clinks.

This is especially the case with the local names given to some of the American birds which utter wild notes, or sounds rather, in the deep forests of that country.

The following figure will give some idea of the form, and also of the markings, of the plumage of this curious bird. The tints of the latter are rather subdued, but the mottlings are exceedingly rich and beautiful.

This bird is of rather light weight for its size, as no small portion of its apparent bulk consists of feathers. Its length is at least ten inches, and the stretch of the wings, which are light and gracefully made, is from sixteen to eighteen. The tail is rather long, rounded, and consists of three feathers. The legs are slender, with the three front toes united as far as the first joint, and the claw on the middle one toothed like a comb. The hind toe is capable of being brought forwards, so as to act in the same direction with the other three. This is not decidedly a perching foot, that is, a foot which can hold on by a twig, while the bird uses his bill in seeking food, or for any other purpose, in a tree. It is simply a resting foot, by means of which the bird is enabled to repose upon twigs and branches until the twilight, and the appearance of its food upon the wing, calls it into activity. This food consists chiefly of beetles which are on or

in the ground during the heat of the day. The goatsucker does not, however, search for them there; for its feet are short, feeble, and but ill adapted for walking. They hold on, however, with considerable firmness while the bird reposes; and in order to protect the muscles which move them from the chilling influence of the twilight air, they are feathered down below the tarsal joints. The use of the pectinated or comb-like claw upon the middle toe has occasioned puzzling and doubting among those writers in natural history who deem it incumbent on them to mention a use for every organ, and form of organ, whether they happen to understand what is the real use of it or not. Some say that it is for the purpose of cleaning the *vibrissæ*, or stiff bristly hairs, with which the margins of the mandibles, especially the upper one, are armed. Others say that it is a real comb, used for clearing the feathers of the bird of those *nirmidæ*, or parasitical insects, with which it is infested. Others again think that this singular form of claw may be useful to the animal in the securing of its prey.

It does not appear that there is very much, or, at least, very obvious truth in any of these. From the remains which are found in its stomach, it does not appear that this bird gives its food any preparation, but that it simply catches and swallows it, just as the day swallows do; and there is perhaps no bird which has a mouth better adapted for the receiving of prey in an entire state. The edges of the mandibles are quite incapable of cutting any thing, because the tips are the only parts that can come together. Besides, bristles or stiff hairs placed near the mouth of any animal, whether bird or any other, are less easily soiled than any other part of its covering. We must therefore pause before we admit this explanation. Then, as to the combing of the feathers, the case is not much better. Feathers are, from their structure, ungainly subjects to which to apply a comb. This comb could not be applied under the wings, which is the favourite place for the *Nirmidæ*; and most birds are in the habit of scratching with their claws such parts of their bodies as they can reach, the head chiefly, whether the claws happen to be toothed or not. Any instrument applied to the foot of a bird, commands so small an extent of the surface of its body, however, that it is not quite consistent with the system of nature to suppose that it should have a special instrument so applied. This hypothesis is also untenable; therefore, with regard to the use made of the pectinated claw in securing the food, we have no direct evidence; because, from the bird preying on the wing, and in the twilight, it is difficult, if not impossible, to see how its prey is caught. But still the probability is against the use of the foot for any such purpose. Instead of being a clutching foot, the foot of the goatsucker is as much the opposite as can well be imagined. In clutching feet the toes are free to their bases, so that the lateral ones may spread outwards; and if any of them is capable of being reversed, it is always the outer one backwards, so that they may act two against two in clutching. But the reversing of the toe in the goatsucker is, as we have said, toward the front, and, therefore, in such a way as to diminish its clutching power. It may be possible, however, that the bird, when it seizes a moth, the expanse of whose wings is too wide for its gape, may use the claw in removing these, either while it holds the moth by the sharp and hooked points of the mandibles, or by holding it against a twig with the one foot, and trimming it with the other. The con-

jectures of Gilbert White, upon such subjects of natural history as came under his own observation, always point to the direction of the truth, unless where deference to the allegations of earlier naturalists cross him, and then he suffers himself to be led astray. His opinion, as will be seen, rather leans to the supposition that the prey is actually taken with the foot, and conveyed to the mouth by that instrument. "On the twelfth of July," says White, "I had a fair opportunity of contemplating the motions of the *Caprimulgus*, or fern-owl, as it was playing round a large oak that swarmed with *Scarabæi*, or fern-chafers. The powers of its wing were wonderful, exceeding, if possible, the various evolutions and quick turns of the swallow genus. But the circumstance that pleased me most was, that I saw it distinctly more than once put out its short leg when on the wing, and, by a bend of the head, deliver somewhat into its mouth. If it takes any part of its food with its foot, as I have now the greatest reason to suppose it does these chafers, I no longer wonder at the use of its middle toe, which is curiously furnished with a serrated claw." As to the fact of the bird repeatedly bringing the foot to the mouth while hawking about for its prey, there can be no doubt, for White is never wrong in a matter of fact of his own observation; but we have already shown that the structure of the foot is against this opinion in the part which he could not observe, namely, in the particular office which the foot performed. Thus we must still regard the use of the pectinated claw as a subject open to future inquiries.

The mouth of the goat-sucker, including the bill, is very curious. Its gape is wider than that of any other bird of these islands. The hard parts of the mandibles occupy only a small portion of the gape; the *vibrissæ*, which are along the remaining part of it, have small muscles attached to their bulbous roots, by the action of which they can be extended outwards, or contracted inwards. Altogether the bill is weak, and, like the bills of the day-swallows, incapable of acting as an offensive weapon against any other bird, however small. The nostrils are contained in tubes, bearing some slight resemblance to those of some of the sea-birds; but what purpose this particular structure of nostril answers in the bird, it is not very easy to say. It is possible that they contribute to a keener sense of smell, which seems to be necessary, because, from the particular manner in which the head is carried when the bird is flying in quest of its prey, it cannot, notwithstanding the largeness of its eyes, see before it. It has indeed been alleged that it turns its eyes so as to look through the integuments of the mouth when flying; but this is too ridiculous to require any serious refutation. Its hearing is no doubt keen, and may serve it in great stead on its nightly excursions. The beetles on which it preys are all noisy in their flight, because the weight of the body, and of the wing-covers or elytra together, require an exceedingly rapid motion of the wings, in order to prevent these animals from falling by their own weight. The large beetles especially, upon which the goat-sucker feeds so much, have great difficulty in taking the wing; and when a tree is thick with chafers, if one shake it, they tumble down like a hail-shower, without being able to get into flight; whereas, if the same were done with naked-winged insects, not one of them would drop. Both beetles and moths have a peculiar scent, and this scent is of course stronger

at night, or in the shadow, than it is in the heat of the sun, because the latter disperses it through the air. The scent may therefore enable this bird to direct the points of its mandibles correctly upon its prey, after the presence of that prey has been made known to it by the ear. But, from the largeness of its eyes, it must also use these to a very considerable extent in making its captures; and as the flight of its prey, whether beetles or moths, is not nearly so rapid as that of the prey of the day-swallows, and it is very dexterous in turning on the wing, there is no doubt that it can wheel round upon the lateral *vane* and so ultimately reach, by the scent, an insect which makes no sound.

We have hinted that the plumage is beautifully mottled. The colours are numerous, consisting of black, brown, rust-colour, ash-colour, and white, with a large white spot on the inner web of the three first quills, in the male bird only. The mottlings in the upper part are well made out in the figure which we have given; and the under part is rusty brown, with waving cross bars of darker colour, and this continues to the extremity of the feathered parts of the legs.

What may be the meaning of the booming or whirring noise which this bird makes when it flies, or whether it be a voluntary sound, or merely produced by the action of the air upon the wide gape and elastic *vibrissæ*, just as the humming of insects is produced by the action of their wings upon the air, we know not; though the goatsucker is not voiceless like these, but has besides various notes by which to express its affections the same as other birds.

This is not a very common bird in any part of the country, but it is much more widely distributed than several others of our summer visitants. It seldom arrives in this country before May, and it continues till about September. The lightness of its wings, the peculiar character of its plumage, and its lightness for its size, must render migration a very easy task to it; and it accordingly extends over great part of the country, being found a considerable way northward in Scotland, where very few of the warblers extend their annual excursions. Though it feeds on the wing, it nestles on the ground, and it spends little of its time in the construction of an artificial nest. Its eggs are deposited under some sort of cover, grass, bushes, or the roots of shrubberies, as it may find most conveniently situated for its feeding-ground. The eggs are only two in number, of a white colour in the ground, and very finely marbled with ash-colour and brown. The ground is also very often its resting-place during those times when it is not preying upon the wing. When thus resting it crouches very close to the surface; and, as its colours are not easily distinguished from those of dry clods, or withered herbage, it in general escapes observation. It does not, however, always take its rest upon the ground, but frequently on a branch of a tree. It chooses a large and horizontal one in preference to a small one which grows erect; and as, when in this situation, it remains motionless, one may pass again and again without observing it.

From the time at which this bird makes its appearance in Britain, and the other temperate parts of Europe, and that at which it retires, we may infer that its special office in nature is to thin the numbers of the larger beetles. In this it has a sort of rival in the kestrel, which, though a hawk, handsome in its

form, and active in its manners, preys a good deal upon beetles in the twilight. According to Selby, the kestrel darts rapidly into the midst of the cock-chafers, where they fly in numbers, and, clutching right and left, seizes them with its talons, and conveys them to its mouth without pausing in its flight. We have already remarked, that the feet of the goatsucker are not well adapted for this purpose, but it has ample compensation in the wideness of its gape and the peculiar construction of its mouth.

In Britain it frequents places which are remote from human dwellings, and generally near the margins of woods or copses; but it is not found in the bleak and elevated districts, where indeed the beetles upon which it feeds are but few, and the large moths still fewer. Generally speaking, it is but thinly scattered over those parts of the country to which it does resort. A single pair appear to be all that usually frequent the same locality, and even these are but rarely seen in company upon the wing. A certain writer on subjects of this kind, who at one time appeared to take particular delight in "pulling plasters off the sores" of others similarly afflicted with himself, mentions having "seen in Scotland eight or ten on the wing together, in the dusk of the evening, skimming over the surface of the ground in all directions, like the swallow, in pursuit of insects, generally with its mouth fully extended." Now, as the bird is exceedingly rare in all parts of Scotland, we greatly doubt whether anybody ever observed more than one at a time in any part of that country; and eight or ten together are out of the question. Indeed, the writer seems to have been aware of this; for, in the sentence which we have quoted, he falls, unawares perhaps, into the singular number, and describes the "eight or ten" only as one. This puts one in mind of Falstaff's men in buckram, only the facetious knight made a climax of it, and this is an anti-climax; so that it more nearly resembles the account of the number of cats given by a young Scotch observer of nature:—"Mither, there are a thousand cats in the back-yard."—"It canna' be true, laddie; naeboddy ever saw sae monie cats a' thegither; and there are no half sae monie in a' the parish."—"Weel, mither, I think there wur' five hundred."—"It canna' be true, laddie."—"Then, mither, I am positive there was our ain cat an' anither aue." We mention this with no invidious intention, and with every disposition to give the most implicit credit to the sentence which called it forth; but really, the known habits of the birds, corroborated as they are by the singular number, repeated in allusion to the swallow, and also to the bird itself, some might be disposed to carry their scepticism a little farther, and doubt whether any goatsucker had been seen at all, and thus take up the concluding admission in the story of a great assemblage of foxes (*Scotticæ* tods), in which the narrator sheltered himself between the horns of the following dilemma—"either a tod or a fern bush." The fact is, that twilight birds are all solitary in their hunting, and so are twilight preying mammalia, with the exception of jackals, and a few others, which give tongue when they are on the chase. Owls, for example, though several pairs may have their nests near each other, are never known to prey in concert; and, with this exception, we at least never heard of any sociality among goatsuckers for the capture either of beetles or moths.

It must be admitted that, besides its singular appearance and curious manners, this is a truly interesting bird; because it is the only one of the genus, or possessing the habit, which is found throughout all of Europe; and it ranges over the greater part of that extent, but only during the summer months. It appears, from all the accounts, to be exceedingly diligent while it is with us; and the very fact of its depositing its eggs on the bare ground, and producing only two at a hatch, and apparently having but one hatch in the year, proves that it requires much of its time for the performance of that office for which it is appointed, in regulating the numbers of those beetles and moths which are understood to be among the most destructive to vegetation, and which appear in the winged state, and fly about in the evenings, only during the warmest season of the year. In America, both North and South, birds of this genus are far more numerous. There are a good many species of them, some migrating into the temperate latitudes during the summer, and others appearing to remain in the tropical forests all the year round. Some of these American species are remarkable for the loudness and peculiarity of their voices. They thus command more attention than many other American birds. Wilson has described the North American ones in his happiest manner, and therefore we shall borrow a few extracts from his delightful pages.

C. vociferus (Whip-poor-Will) is perhaps the most interesting of all the species which appear in North America. Some naturalists have confounded it with two other species, the Carolina and the American, from both of which it is distinct in appearance and in voice. The following is Wilson's description of it:—"Whip-poor-Will is nine inches and a half long, and nineteen inches in extent; the bill is blackish, a full quarter of an inch long, much stronger than that of the night-hawk, and bent a little at the point, the under mandible arched a little upward, following the curvature of the upper; the nostrils are prominent and tubular, their openings directed forward; the mouth is extravagantly large, of a pale flesh colour within, and beset along the sides with a number of long thick elastic bristles, the longest of which extends more than half an inch beyond the point of the bill, end in fine hair, and curve inwards; these seem to serve as feelers, and prevent the escape of winged insects; the eyes are very large, full, and bluish black; the plumage above is so variegated with black, pale cream, brown, and rust colour, sprinkled and powdered in such minute streaks and spots, as to defy description; the upper part of the head is of a light brownish grey, marked with a longitudinal streak of black, with others radiating from it; the back is darker, finely streaked with a less dense black; the scapulars are very light whitish ochre, beautifully variegated with two or three oblique streaks of very deep black; the tail is rounded, consisting of ten feathers, the exterior one an inch and a quarter shorter than the middle ones, the three outer feathers on each side are blackish brown for half their length, thence pure white to the tips, the exterior one is edged with deep brown nearly to the tip; the deep brown of these feathers is regularly studded with light brown spots; the four middle ones are without the white at the ends, but beautifully marked with herring-bone figures of black and light ochre finely powdered; cheeks and sides of

the head of a brown orange or burnt colour; the wings, when shut, reach scarcely to the middle of the tail, and are elegantly spotted with very light and dark brown, but are entirely without the large spot of white which distinguishes the night hawk; chin black, streaked with brown; a narrow semicircular line of white passes across the throat; breast and belly irregularly mottled, and streaked with black and yellow ochre; the legs and feet are of a light purplish flesh colour, seamed with white, the former feathered before nearly to the feet; the two exterior toes are joined to the middle one, as far as the joint, by a broad membrane; the inner edge of the middle claw is pectinated, and, from the circumstance of its being frequently found with small portions of down adhering to the teeth, is probably employed as a comb to rid the plumage of its head of vermin, this being the principal and almost only part so infested in all birds."

This singularly noisy species is migratory in the United States, where it is first heard about the middle or toward the end of April. Its notes are as familiar to the people there as those of the cuckoo are in Britain. They resemble as nearly as possible the words "whip-poor-will," the middle one short, and the first and last very loud. At first they are heard from the depths of woods in lonely places; but they soon approach near dwelling-houses, and make such a noise during morning and evening twilight, and all night long if the moon shines brightly, and its clamour is so loud, that strangers find difficulty in sleeping. The inhabitants, however, welcome it as the harbinger of good weather, much in the same way as we welcome the cuckoo. As the season advances, it gets very familiar, and perches close by the house, or even on the house-top. From its singular voice, and the twilight gloom in which that voice is uttered, the ignorant regard it as a harbinger of some calamity to the family upon whose dwelling it takes its post. We must not be surprised at this, either on the part of the native Indians or on the part of the more ignorant European settlers; for there are still many parts of our own country where a magpie, perching on the top of the house, throws the whole family into the greatest apprehensions. When two or more male birds are near to each other, which is often the case, they sing in rivalry, as most songsters do; and when they raise the pitch of their voices, they also hurry the time. Wilson thus describes their manners.—"They fly low, not more than a few feet from the surface, skimming about the house and before the door, alighting on the wood pile, or settling on the roof. Towards midnight they generally become silent, unless in clear moonlight, when they are heard with little intermission till morning. If there be a creek near, with high precipitous bushy banks, they are sure to be found in such situations. During the day they sit in the most retired, solitary, and deep shaded parts of the woods, generally on high ground, where they repose in silence. When disturbed they rise within a few feet, sail low and slowly through the woods for thirty or forty yards, and generally settle on a low branch or on the ground. Their sight appears deficient during the day, as, like owls, they seem then to want that vivacity for which they are distinguished in the morning and evening twilight. They are rarely shot at or molested; and, from being thus transiently seen in the obscurity of dusk, or in the deep umbrage of the woods, no won-

der their particular markings of plumage should be so little known, or that they should be confounded with the night hawk, which in general appearance they so much resemble. The female begins to lay about the second week in May, selecting for the purpose the most unfrequented part of the wood, often where some brush, old logs, heaps of leaves, &c., had been lying, and always in a dry situation. The eggs are deposited on the ground, or on the leaves, not the slightest appearance of a nest being visible. They are usually two in number, in shape much resembling those of the night hawk, but having the ground colour much darker and more thickly marbled with dark olive."

Most European describers of birds have confounded this species with two others, from which it is distinct as well in its manners as in its haunts. Dry and elevated places are the chief resort of this one, whereas the others prefer grounds of a different character. The song of the male does not continue above a month or five weeks, for it ceases as soon as the young are hatched; though it begins again, but more feebly, and of shorter duration, in September, before the birds begin to move southwards. The young, while incapable of flight, conceal themselves by lying motionless among the clods or the withered leaves; and the following anecdote will show that, as is the case with most birds which leave their young on the ground, the female has recourse to a good deal of stratagem in order to entice supposed enemies away from them. "In traversing the woods one day, in the early part of June," says Wilson, "along the brow of a rocky declivity, a whip-poor-will rose from my feet, and fluttered along, sometimes prostrating herself, and beating the ground with her wings as if expiring. Aware of her purpose, I stood still and began to examine the space immediately around me for the eggs or young, one or other of which I was certain must be near. After a long search, to my mortification, I could find neither; and was just going to abandon the spot, when I perceived somewhat like a slight mouldiness among the leaves, and, on stooping down, discovered it to be a young whip-poor-will, seemingly asleep, as its eyelids were nearly closed, or perhaps this might only be to protect its tender eyes from the glare of day. I sat down by it on the leaves, and drew it as it then appeared. It was probably not a week old. All the while I was thus engaged, it neither moved its body nor opened its eyes more than half, and I left it as I found it. After I had walked about a quarter of a mile from the spot, recollecting that I had left a pencil behind, I returned and found my pencil, but the young bird was gone."

C. Carolinensis.—Chuck-will's-Widow. This species is not very correctly named the Carolina goatsucker; for it extends into South America, though it never reaches the northern parts of the United States in its summer migrations. It appears rather earlier than the last-mentioned species; and though its note is different, and it is a much larger bird than whip-poor-will, they haunt nearly the same sort of places. This one, however, keeps more constantly to the woods than the former, and therefore is less frequently seen. The eggs are deposited on the ground. They are two in number, and of equal thickness at both ends, as is the case with the eggs of all this genus. They are about the size of pigeons' eggs, of a dull olive, mottled with darker markings. This is the one which, in colour at least, most resembles the European goat-

sucker; but still they are perfectly distinct species, as will be seen from the description. "This species is," says Wilson, "twelve inches long and twenty-six in extent; bill yellowish, tipped with black; the sides of the mouth are armed with numerous long bristles, strong, tapering, and furnished with finer hairs branching from each; cheeks and chin rust colour, speckled with black; over the eye extends a line of small whitish spots; head and neck very deep brown, powdered with cream, rust, and bright ferruginous colour, and marked with long ragged streaks of black; scapulars broadly spotted with deep black, bordered with cream, and interspersed with whitish; the plumage of that part of the neck which falls over the back is long, something like that of a cock, and streaked with yellowish-brown; wing quills barred with black and white rust; tail rounded, extending about an inch beyond the tips of the wings; it consists of ten feathers, the four middle ones are powdered with various tints of ferruginous, and elegantly marked with fine zig-zag lines, and large herring-bone figures of black; exterior edge of the three outer feathers barred like the wings; their interior varies for two-thirds of their length, are pure snowy white, marbled with black, and ferruginous at the base; this white spreads over the greater part of the three outer feathers near the tips; across the throat is a slight band or mark of whitish; breast black, powdered with rust; belly and vent lighter; legs feathered before nearly to the feet, which are of a dirty purplish flesh colour; inner side of the middle claw deeply pectinated. The female differs chiefly in wanting the pure white on the three exterior tail feathers, these being more of a brownish cast."

This bird arrives in the extreme south of the United States of America about the middle of March, and, like the former, it very speedily gives notice of its arrival by uttering its singular call, which bears a striking resemblance to the words that have been adopted as its name. The different parts of this singular cry are uttered with a distinctness approaching to articulation. But it is only during the night that they are heard, for, like the rest of the genus, it remains perfectly mute until sunset. If the night is moonless, its voice is suspended during the dark part; but in bright moonshine, it is incessant the whole night over.

C. Americanus (The Night-Hawk). The specific name, *Americanus*, is by no means very happily applied to this, or indeed to any other species of the genus, for this and the two preceding ones appear equally in the United States; and in the tropical parts of the American continent there are many more. Generally speaking, this species inhabits more marshy localities than the others, and it also flies higher, making in that respect an approach to the day swallows. Though called the night-hawk, it appears to be less nocturnal than some of the others, and often dashes over towns and cities, something in the manner of the swift, but with far more varied motion. They arrive in their northern localities toward the end of April, and the eggs are deposited in the middle of May. They are two in number, as in the other species, of a dull bluish-white colour, mottled with small spots of olive-brown. The eggs, though without any form of nest, are always deposited in a dry place, and near trees, upon the branches of which the male, and frequently also the female, repose during the day, sitting lengthwise upon the branch, so as not to be easily discovered. But though the pair are usually

found in the same neighbourhood, they seldom if ever repose in the same tree.

The conduct of the male, while watching the female and the eggs, is so graphically described by Wilson, that we cannot resist quoting the passage. "As soon as incubation commences," says he, "the male keeps a most vigilant watch around. He is then more frequently seen playing about in the air over the place, even during the day, mounting by several quick vibrations of the wings, then a few slower, uttering all the while a sharp harsh squeak, till, having gained the highest point, he suddenly precipitates himself head foremost, and with great rapidity, down sixty or eighty feet, wheeling up again as suddenly; at which instant is heard a loud booming sound, very much resembling that produced by blowing strongly into the bung-hole of an empty hogshead, and which is doubtless produced by the sudden expansion of his capacious mouth, while he passes through the air. He again mounts by alternate quick and leisurely motions of the wings, playing about as he ascends, uttering his usual hoarse squeak, till, in a few minutes, he again dives with the same impetuosity and harsh sound as before. Some are of opinion that this is done to intimidate man or beast from approaching his nest; and he is particularly observed to repeat those dives most frequently around those who come near the spot, sweeping down past them, sometimes so near and so suddenly, as to startle and alarm them. The same individual is, however, often seen performing the same manœuvres over the river, the hill, the meadow, and the marsh, in the space of a quarter of an hour, and also towards the fall when he has no nest. This singular habit belongs peculiarly to the male. The female has, indeed, the same harsh note, and much the same mode of flight; but never precipitates herself in the same manner as the male. During the time she is sitting, she will suffer you to approach within a foot or two before she attempts to stir, and, when she does it, it is in such a fluttering trembling manner, and with such appearance of a lame and wounded bird, as nine times in ten to deceive the person, and induce him to pursue her. This 'pious fraud,' as the poet Thomson calls it, is kept up until the person is sufficiently removed from the nest, when she immediately mounts and disappears. When the young are first hatched, it is difficult to distinguish them from the surface of the ground, their down being of a pale brownish colour, and they are altogether destitute of the common shape of birds, sitting so fixed and so squat as to be easily mistaken for a slight prominent mouldiness lying on the ground. I cannot say whether they have two broods in the season; I rather conjecture that they have generally but one."

As we already said, this bird is not so decidedly nocturnal as some of the other species. In gloomy weather it wings its aerial flight the whole day long; but when the weather is clear, it does not come into activity till about an hour or two before sunset. Contrary to the habit of many of the others, however, it appears to prefer the sun to the shade, for in the clearest summer days it is occasionally out, and, when reposing upon a branch, they are fond of doing so in the heat of the sun. When wounded or captured, they put on a semblance of defence, by gaping to the full extent of their wide mouths, and emitting a sort of hiss. They also endeavour to strike with their wings; but they never offer to use either the bill or the claws.

As this species is also confounded with whip-poor-will, in many of the books, it is desirable to be in possession of Wilson's highly discriminating description of it. His accounts of the three North American species of goat-suckers are indeed peculiarly interesting, as placing in the clearest light the distinctions of three of the most remarkable birds of that part of the world. "The night-hawk," says he, "is nine inches and a half in length, and twenty-three inches in extent; the upper parts are of a very deep blackish brown, unmixed on the primaries, but thickly sprinkled on the back, scapulars, and head with innumerable minute spots and streaks of a pale colour, interspersed with specks of reddish; the scapulars are barred with the same, also the tail coverts and tail, the inner edges of which are barred with white and deep brownish black for an inch and a half from the tip, where they are crossed broadly with a band of white, the two middle ones excepted, which are plain deep brown, barred and sprinkled with light clay; a spot of pure white extends over the five first primaries, the outer edge of the exterior feather excepted, and about the middle of the wing; a triangular spot of white also marks the throat, bending up on each side of the neck; the bill is exceedingly small, scarcely one-eighth of an inch in length, and of a black colour; the nostrils circular, and surrounded with a prominent rim; eye large and full, of a deep bluish black; the legs are short, feathered a little below the knees, and, as well as the toes, of a purple flesh colour, seamed with white; the middle claw is pectinated on its inner edge, to serve as a comb to clear the bird of vermin; the whole lower parts of the body are marked with transverse lines of dusky and yellowish. The tail is somewhat shorter than the wings when shut, is handsomely forked, and consists of ten broad feathers; the mouth is extremely large, and of a reddish flesh colour within; there are no bristles about the bill, the tongue is very small, and attached to the inner surface of the mouth. The female measures about nine inches in length and twenty-two in breadth; differs in having no white band on the tail, but has the spot of white on the wing; wants the triangular spot of white on the throat, instead of which there is a dully defined mark of reddish cream colour; the wings are nearly black, all the quills being slightly tipped with white; the tail as in the male, and minutely tipped with white; all the scapulars, and whole upper parts, are powdered with a much lighter grey."

South America contains many species of goat-sucker, besides those which we have already enumerated, as paying their annual visit to the northern part of that continent. In the warm regions of America they are indeed highly characteristic birds; and the same may perhaps be said of them in Africa, and even in New Holland, which, though rather scanty in its mammalia, is a very remarkable country for the numbers and character of its birds. We shall give little more than a running catalogue of a few of the goatsuckers of these parts of the world, beginning of course with South America.

C. cornutus (the Urutau) is a species mentioned by D'Azzara, as frequenting Paraguay from October till February, which is the summer of the year in that part of the world. It gets the name of *cornutus*, or horned, from a tuft of feathers which grow over each eye, and which fancy might convert into a species of horns, in the same manner as the tufts upon the heads in some species of owls are called by the same name.

The upper parts of this species are brown, variegated with russet, and a portion of the under part is of the same colour but lighter. The belly is whitish. The quills and tail-feathers are brown, barred across with white. The throat, the fore neck, and the breast, are russet, but with black points to the feathers of the latter. The middle toe is without any tooting, and the feathers of the head, just over the eyes, are stiff, and form a sort of aigrette, from which the specific name is taken. They are decidedly tree birds; and the natural historian of Paraguay mentions that they are seldom seen on the ground, or indeed in any situation except on the trees. They adhere to the inequalities of the bark, in a style not very dissimilar to that of the woodpeckers; and they are rarely if ever seen upon the ground. They come in pairs, and breed in Paraguay, as indeed is the case with all migratory birds, which invariably breed in those places of their range which are most distant from the equator. The pair keep closely associated during the time that they reside in that part of America; and though they sometimes settle upon separate trees, they always, upon such occasions, call and answer to each other in a peculiarly melancholy sort of tone. The eggs are two in number, with a pale brown ground, and thickly mottled with darker spots of the same colour. The natural historian of Paraguay says that these eggs are deposited not in any sort of formal nest, but in a cleft of a tree, and that the female hangs over them in the act of incubation. Other reports state that the eggs are attached to the tree by some glutinous substance; but there is probably no more truth in this than there is in the similar allegation of some sea-birds gluing their eggs to the rocks. The manners of these birds, and indeed those of most of the South American species of the genus, are, however, but little understood.

C. psalurus (The scissors-tailed goatsucker). This is another South American species, for the first and the only accurate account of which we are indebted to the naturalist of Paraguay. He describes them as being rare, and appearing in Paraguay only during the middle of winter, which would lead one to conclude that the birds spend their summer in parts of America still farther to the south. The upper parts are ash-colour, mottled with brown and black; and the under parts are pale ash-colour, with black cross bars. The sides of the head, and over the eyes, are white, clouded with grey; the throat and breast are reddish grey, streaked with red and black; and there is a large band of bright yellow across the lower part of the neck; the coverts of the wings are beautifully mottled with brown ash-colour, black and red; the outer web of the first quill is red, and the other quills are chiefly grey; the tail-feathers are also grey, very handsomely marked with black; the two lateral feathers of the tail are of great length, equal to one and a half times the total length of the bird; they are very handsome, broad in their webs at the basal part, but tapering off gracefully toward the points; the feathers next them are gradually shorter until the middle of the tail is arrived at, in which again the feathers are rather longer, though still short as compared with the external ones; the length of the bird, exclusively of the tail-feathers, varies from fourteen to sixteen inches. The female is smaller than the male, has the colours less intense, and the external tail-feathers not nearly so much produced. This

is one of the most interesting of that curious genus of birds to which it belongs. Its colours, though not gaudy, are exceedingly beautiful, and it possesses great power over the long feathers of the tail, which, as it skims over the waters, it opens and shuts something after the manner of a pair of scissors; and it is from this form of the tail and habit in the use of it, that the bird gets the name of scissor-tailed. Those produced feathers are characteristic of maturity in the male bird; but it is not known whether they are or are not a nuptial livery, as the birds have not been observed in the same locality during the entire course of the year. They are found in Brazil as well as in Paraguay; and their singular form and highly interesting manners render them subjects of which it would be desirable to know a good deal more.

C. manurus. This species bears some slight resemblance to the former; but it is a smaller bird and lighter in the plumage, the ground colour being bright grey, marked with black spots, and powdered with small dots of white on the wings. The lateral feathers of the tail are not so much produced as in the former species; but still, in the adult male, they are fully five inches longer than the intermediate ones.

To enter farther into an enumeration of the species of this genus, which inhabit the extensive forests of South America, would be merely to increase the list of names and colours without adding to the quantity of information. Many have been enumerated by describers; but they have, in many instances, been single specimens, which had no history, and answered no other purpose than swelling the list of museum catalogues. We shall, therefore, only farther notice a few of the more remarkable of those species which are found in the warm parts of the eastern continent, some of which, at least, appear to inhabit Africa and India.

C. macrodipterus. This species is a native of Africa, from which it has frequently been brought to Europe as exhibiting one of the most singular specimens of bird with which we are acquainted. Western Africa is, we believe, the place from which it has been chiefly obtained; but its manners are as obscure as its form is singular. In its general form, colours, and markings, this bird bears a strong resemblance to the common goatsucker of Europe, being mottled with ash colour, brown, yellow, and black on the upper part, rather paler on the under, with white spots on the wings. The remarkable peculiarity of it, however, consists in two supplemental feathers which, issuing from the wings, extend considerably more than double the length of the bird, for the greater part of their length they are without any webs; but at the extremity they have a broad web externally and a narrow one internally, so that they resemble a pair of paddles. What use the bird may make of such furnishings it is impossible to say. That they have a use cannot be doubted, for nothing in nature is made in vain; but they are so different from all the ordinary appendages of birds, that no opinion respecting them can be given. The scissor-tailed species, and all the others which have the tail feathers long and much power of motion in them, are remarkable for the energy which they display in the working of these instruments; but it is difficult to see for what purpose two feathers issuing from the wings as they do in this bird can be worked. The species last mentioned is sometimes also termed the Leone, or Sierra Leone

goatsucker, from its being met with in that part of Africa.

C. pectoralis. (The Collared Goatsucker) is described as being a native both of India and Africa. Le Vaillant describes it as being common in some parts of the latter country, and as causing itself to be heard from the loudness and peculiarity of its nocturnal notes. It was in the southern part of the Cape territory, where the bird was described by the naturalist whose name we have mentioned. The song of the male, if song it can be called, is chiefly delivered while the female is sitting. It is a nocturnal song, not beginning till about an hour after sunset, which includes a large portion of the twilight in that country; and in places where the birds are numerous, the noise which they make is very disagreeable to strangers. The female makes no regular nest, but deposits her eggs on the bare earth, sometimes in a regular footpath; and she sits so closely on them, and so much resembles the parched surface of the ground, that she may be passed without being observed. The eggs are two in number, of a white colour, with very few markings, and they are so brittle, that they can scarcely bear handling. During the day the male often takes the place of the female, in order that she may procure a supply of food; but it is understood that she sits closely during the time that he is uttering his cry. If the eggs have been touched, Le Vaillant says that the birds hide them; and the account which he gives is so circumstantial, that we shall quote it with some slight alterations. In order to witness this operation, he first handled the eggs, laid them down in their place, and then concealed himself in a tree to watch the result. The first of the birds which came to the eggs was the female, and she alighted on the ground close by them, and then approached slowly and deliberately, and having, by what instinct it does not appear, ascertained that they had been touched, she walked several times round the nest with her bill close to the eggs, and her breast close to the ground, beating the earth at the same time with her wings, and uttering several peculiar cries. This appeared to be the signal for the male to approach her, for he immediately approached, uttering the same cry, and joined her in the same operations. Both then got on the wing, and having flown several times round the eggs, each seized one in its mouth, and quickly disappeared.

C. fuscifer is described as another African species, bearing some resemblance to the forked-tailed one of Brazil, and remarkable for its large size, as well as for the deep forking of the tail. The entire length of the bird is upwards of two feet, and the wings extend forty inches from tip to tip, so that, long as the tail is, they reach to the extremity of it when closed. In the length of its wings, and the forking of its tail, this bird bears a considerable resemblance to the swallow. There is also something very peculiar in the structure of the bill. The gape is very wide, but the upper mandible is narrowed at the tip till the extremity of it bears more resemblance to a claw than to the point of an ordinary bill. It also shuts very closely, by an edge of the lower mandible which encloses the sides of the upper upper one; and toward the extremity receives it into a sort of groove, which however, terminates, and leaves a portion of the hooked point of the upper one projecting over. There is, in fact, more provision made for the closing of the bill of this bird than for that of any other bird of which we have

any knowledge; and this closing is so complete, that when the bird is seen in profile, the bill seems to be a very small one. Le Vaillant describes this bird as being observed by him in the Namaqua country, northward of the settlement of the Cape, where the Garipe, or Orange river, by much the largest in Southern Africa, falls into the Atlantic. The mode in which he says he procured them gives a curious display of the characters of these birds. Whilst hunting one day on the banks of one of the branches of the Orange river, accompanied by his native attendant, they were overtaken by a violent storm of wind and rain, which obliged them to take shelter under some large mimosas. From this position they observed in their vicinity a huge tree quite dead, with its trunk almost entirely hollowed out, to which aperture a large opening communicated. They approached this tree in expectation of finding some insects under the bark; but, as they advanced, they heard a low humming noise issue from the cavity. Dreading that this sound might proceed from a nest of serpents, or other noxious animals, that might be lurking there, they took some precaution in exploring the place. To their surprise, however, they encountered only two large birds, which they drew forth one after another. M. Le Vaillant kept them alive for two days, but the light of the sun affected them so much that they did not attempt to escape in the day time; but, in the darkness of night, they made desperate efforts to get out of the basket in which they were kept captive.

There are some species in Australia, one of which has the head furnished with a crest of produced feathers, and some of the tints of its plumage are lighter than those of most of the genus, but otherwise it presents nothing worthy of very particular notice, and its manners are obscure and little known.

PODARGUS. These form the remaining genus of the night swallows, or rather of those birds which prey something after the manner of swallows, and generally in the twilight. It will be seen, from the account which we have given of the leading species of the former genus, that birds of this description are chiefly confined to those parts of the world which have their seasons strongly contrasted by alternating drought and rain; the former continuing with such intensity and heat as to produce a desolation something resembling that of winter, and the latter giving an excessive stimulus first to vegetable and then to animal life; the season of the last of which is later than that of the other. In consequence of this the night air is, at certain seasons, literally crowded with insects, upon which both genera of this family of birds feed in great numbers.

The genus *podargus*, as at present established, does not contain nearly so many species as the preceding one; but as there is a sort of gradation in that which forms the leading character, the line of distinction is not very easily drawn. One very curious species, which is described as the Trinidad goatsucker, seems to be of doubtful reference in this respect, and therefore we shall content ourselves with a few words of general description, without a positive reference of the bird to either genus.

Though Trinidad is in itself a comparatively healthy and tranquil island, there are violent contests of the elements in that portion of water by which it is divided from the main land of South America. The lower valley of the Orinoco then is subject to violent

floods, which cover, at one season of the year, a large extent of surface which is dry at other times. The navigation of this passage is exceedingly dangerous; and therefore, though the natural productions of the banks and islands are matters of considerable interest, they are very little known. We quote the original description of the Trinidad goatsucker, as communicated to Dr. Latham by Mr. Thomson. "These birds inhabit coves of the islands forming the Bocata, an entrance into the Gulf of Paria, accessible only at the very lowest ebb tides, and in moderate weather; and as they are never observed on the wing in day-time, most probably, like the rest of the genus, they seek their food in the absence of the sun. Here they breed during the early part of the spring; and it is at the time of new and full moons, in April and May, that the people who are acquainted with these coves, resort thither to take the young, and such of the birds as they can knock down with sticks. They have a strong and a disagreeable fleshy smell, but some people compare it to that of the cockroach; when dressed they look like a round lump of fat, the little flesh there is tasting more like that of a sucking-pig than any other, but yet with a flavour and lusciousness perfectly its own. But what is most extraordinary is, that in a family supposed to be wholly insectivorous, this should constitute a single and solitary exception, and be found to subsist, at least during the breeding season, entirely on fruit; for, on examining the stomachs of a dozen of them, young and old, no other species of food whatever but the fruit of the palm appeared. The collector in ornithology will find a very troublesome task in preserving this bird, as the skin adheres with uncommon closeness and tenacity to the granular fat, which every where covers the body, and which liquifies under the touch."

It is by no means improbable that some at least of the singular birds which Humboldt and his associates met with in their researches among the very extraordinary ravines and chasms, which seam the northern slopes of the Peruvian Andes, and are cleft to depths which defy the beams of even a tropical sun, belong to this class. The notices of those birds were, however, chiefly obtained from the Indians, and their accounts cannot be implicitly relied on. Indeed we want much farther research into the natural history of that singular portion of the earth's surface before we can form an accurate estimate of any or part of its zoology.

Whether any of those birds, whose history is at present so shadowy, may belong more correctly to the genus *Podargus*, or the genus *Caprimulgus*, or whether they may be something intermediate between the two, are points which we are not at present in a condition for settling. The prominent characters of *Podargus* consist in the stronger nature of the bill and the enlargement of the claws. They may be described as having the bill hard, stout, and of an entirely horny substance, instead of being soft in part like those of the typical goatsuckers. The breadth of the bill at the basal part is excessive, so that the gape is actually broader than the measure of the forehead. The keel on the upper mandible is rounded, curved from its origin, and much hooked at the tip. Both mandibles are much dilated at the sides, and the angle of the gape extends to a considerable distance behind the eyes. The lower mandible is of hard texture, straight in the greater part of its length, but slightly hooked at the tip, which is furnished with

a groove to receive the hook of the upper mandible. The nostrils are linear, placed at some distance from the base of the bill, nearly closed by a horny plate, and concealed by the feather of the front. The tarsi are short, and the feet have four toes, three in front. The internal one is united to the middle as far as the first joint; but the external is free, and the hind toe is capable of being reversed. The claws are not very long, but they are hooked and sharp, and that of the middle toe is not pectinated. The first and second quills are shorter than the third and the fourth is the longest in the wing.

These birds were unknown as a genus until they were partially investigated by Humboldt in the Andes, and by Horsfield in the eastern continent. The species alluded to by the former of these authors is probably the Trinidad goatsucker, of which we have taken some notice; but the eastern species have been more carefully examined, and their characters are more clearly established. The whole of them are twilight birds, inhabiting caves and the thick shades of tropical forests, which are seldom visited by any human beings except the most savage tribes. Where they live, twilight may be said to reign all day long; and they rarely come into situations where the air is free and the sun bright. They are understood to subsist entirely upon insects, especially moths and beetles of the largest size, which they seize with the beak while upon the wing. Some naturalists, who are perhaps rather fond of tracing what are called affinities, have described these birds as forming an intermediate or connecting link between the goatsuckers and the owls. This relation is not, however, borne out by the habits of the two races. They belong geographically to different departments of the earth; their prey is different, and they catch it in a different manner. Small mammalia are the proper food of the owls, and they come upon these by stealth, and, of course, always secure them upon the ground. Insects again are the food of the *Podargi*; and they seize these chiefly on the wing. Those differences of habit very naturally point to corresponding differences of geographical situation. The polar parts of the world are the head-quarters of those small rodent mammalia, upon which owls in great part feed; and, therefore, according to that law of nature by which the prey and the preyer are invariably brought into juxtaposition in the same locality, the polar parts of the world are also the head-quarters of the owls. But the tropical regions are the head-quarters of all insectivorous birds, being the head-quarters of those insects upon which the birds feed.

Notwithstanding the abundance of insects, chiefly small ones, which are found in the polar forests, and hovering over the polar marshes during the summer, there is not one to be found there during the winter, or in high latitudes, for nearly nine months out of the twelve. There is therefore no permanent place for an insectivorous bird in those high latitudes; and of course there is not one that remains there, though a few pay their annual visits during the short summer. It is very different in the dark caves and thick damp forests of polar countries. Such places do not feel the scorching heat which brings desolation on the dry plains; they have always heat enough, and also moisture enough, for an abundant production of insects; and consequently the insectivorous birds dwell permanently in them, enjoying a perpetual harvest, and rearing their broods indiscrimi-

minately at any time, without the slightest reference to any change of seasons. This is the character of the bird, which is most decidedly marked in the *podargi*; and any one who reflects upon the subject, with even a moderate degree of attention, will at once see, that in this there is not the slightest affinity or approach to the character of the owls. It is of great importance to keep in view the geographical tendencies of animals; because, whatever resemblance there may be in the structures of individual parts, we always find that the essential characters of the animal are so closely connected with its geography, that the one may in great part be made an index to the other; and this is one of the ways in which natural history is made to conduce most essentially to the advancement of general knowledge; a subject of far more consequence than the introduction of any one artificial system, however plausible that system may be, into any single department either of the animal world or of the vegetable.

We have already remarked, that the natural history of this particular genus of twilight feeders upon insects is very obscure; and we may add, that it is highly probable that we are not yet acquainted with the half, or probably even the hundredth part of the number, so that it is impossible to carry this very curious part of the geographical history of birds to that extent which would be desirable; we must, consequently, restrict our notices to the one or two species which have been ascertained by competent authorities.

P. cornutus.—The horned *Podargus*. This appears to have been the species found in the woods of Java by Dr. Horsfield. It is a very singular-looking bird, from the great width of its gape, the forward position of the eyes, and the produced feathers with loose and straggling webs, which stick out from the sides of the head. Its upper parts are of a greyish brown colour, mottled with black and white; the forehead is covered with brown feathers, with shafts terminating like hairs, and the sides of the head with black feathers, of which the webs are loose and open, and, though less produced, bear no inconsiderable resemblance in their texture to the feathers on some of the birds of paradise. What may be the use of such feathers in the economy of the bird is not known, but, as they cover the external openings of the ears, it is not unlikely that they are, in some way or other, connected with the sense of hearing. The lower part of the neck is crossed by a white band, and there is a white spot upon the termination of each of the lesser coverts of the wings; the quills are brown, spotted on their outer webs with dark brown and russet; the tail-feathers are also brown, staged at their extremities, mottled with black, marked with eight bars, and the external ones are spotted with reddish white; the throat is brown, marked with small longitudinal lines; the centre of the breast is nearly white, marked with a large gorget of brown and black; the rest of the under parts are whitish, delicately streaked with lines of black and russet. The length of the bird is about eight inches, and its weight is but trifling even as compared with its size. Of its nest-building, or other habits, little or nothing is known. In the case of this, as well as of many other birds which have tufts of produced feathers on the sides of the head, the name horned is very inaptly applied, for in birds these additions to the head never consist of anything but feathers.

P. cinereus, is a New Holland species, the prevail-

ing colour of which, as its name imports, is ashen grey. It is, however, very much mottled by other colours. It is about the size of a jackdaw, or rather, perhaps, a little larger. The spots which mark it are chiefly black and white; and it differs from the Javanese species in having the bill and feet black.

Such are a few of the particulars known respecting one of the most singular families of the feathered tribes.

NYMPH. A name sometimes given to the pupa stato of various insects. See **INSECT**, **CHRYsalis**.

NYMPHÆACEÆ. A natural order containing four genera, viz., *Nelumbium*, *Euryale*, *Nymphaea*, and *Nuphar*. They are all aquatics, and some of them bear very splendid flowers. They occur in almost every pool, canal, or slow-running stream over all India and China; and the hardy nuphar is common in all similar situations in Europe.

Nelumbium and *Nymphaea* are the normal genera and types of the order. These, although essentially distinct, are in many particulars so much alike, that they were formerly considered but one species of one and the same genus. Collectively considered, the *Nelumbianæ* are aquatic *Ranunculinae* with prostrate stems, which extend themselves in the mud, peltate, or cordate fleshy leaves, which mostly float on the water, sepals, petals, and stamens passing into each other, embryo excluded or without the albumen, but inclosed in a membranous sac. The inflorescence is solitary; the peduncles long, varying in length with the depth of the water, round, and ebracteate. The flowers are large and showy, regular and united.

The Pythagorean bean is supposed to have been the fruit of *Nelumbium speciosum*, or the water lotus, formerly a native of Egypt and other warm regions in Africa and Asia, but not now to be found in the Nile, its most celebrated habitat of antiquity. It was called *Cyamus* by the ancients, and its present generic name is an alteration of the Cingalese word *Nelumbo*.

The creeping jointed subaqueous stem or rhizoma, as well as the seeds, are eatable, and they are said to be both savoury and wholesome. In China the plant is called *Lien-fui*; and peeled seeds and slices of the rhizoma, with the kernels of apricots and walnuts, alternated with layers of ice, were frequently presented to the British ambassador and his suite, at breakfasts given by some of the principal mandarins.

The seeds of the *N. rubra* and *N. lotus* are eatable. The *odorata* and *alba* have been occasionally employed medicinally as astringents, but their use is almost obsolete, being seldom resorted to as styptics, and only occasionally chewed by singers to relieve relaxation of the uvula and soft palate, give firmness to the vocal organs, and clear the voice.

The tropical species are cultivated and flowered in our stoves, planted in tubs of muddy soil, and kept flooded with water during the growing season, but kept drier while dormant. They are raised from imported seeds, or by dividing the root.

NYMPHALIDÆ (Swainson). A family of diurnal butterflies, comprising those species which have the fore legs rudimental, the pupa only suspended by the tail, and not girt round the body; the caterpillar cylindrical, spinose, and with two short anal spines; and the antennæ with a distinct club, and not hooked at the tip. These butterflies are distinguished by their strength of body and powerful nerves of the wings, giving great rapidity of flight. Their colours are generally brilliant and variegated, often orna-

mented with beautiful eye-like marks, or spotted with silver on the under side. The species are exceedingly numerous, especially in extra European countries, and their size generally far exceeds that of the *Hesperidæ* or *Lycænidæ*, although often smaller than the *Papilionidæ*. The genera are *Cethosia*, *Argynnis*, *Melitæa*, *Vanessa*, *Cynthia*, *Nymphalis*, *Libythea*, *Biblis*, *Melanitis*, *Morpho*, *Pavonia*, *Brassolis*, *Eumonia*, *Eurybia*, *Hipparchia*, *Fabricius* (*Satyrus*, *Latreille*), *Apatura* and *Limenitis*, those marked in italics containing British species. See the articles **BUTTERFLY**, **LEPIDOPTERA**, and **DIURNA**.

NYMPHON (Fabricius). A remarkable genus of apterous insects, belonging to the class *Arachnida* and order *Podosomata* of Leach (*Aporobrachnia* of Latreille) having the body small and linear, the legs very long, with a pair of antennal claws, and two palpi. These are extraordinary marine animals resembling spiders, but having only four pairs of legs; they are found amongst various aquatic plants under stones, &c. They appear to be destitute of any appearance of breathing pores, whence Latreille's name *Aporobrachnia*. The females are furnished with an additional pair of short filamentous processes to which the eggs are attached. There are several British species, but their characters have not yet been satisfactorily determined. Dr. Leach has figured two species, *N. gracile* and *femoratum*, in the *Zoological Miscellany*.

NYSSA (Linnæus). A genus of North American trees, belonging to *Santalacææ*. The fruit of *N. canadensis* are preserved and used instead of olives. *N. denticulata* is a lofty tree of great beauty. In British collections they answer the purpose of large shrubs, and grow best in damp situations. They are increased by layers.

OAK is the *Quercus robur* of Linnæus, the British oak. Of this most important genus of forest trees, there are sixty-one species and twenty-two varieties, named in our books. There are two, but very nearly allied, sorts met with in woods: one with the acorns sitting close upon the twig on which they grow, hence called *Q. sessiflora*; the other bearing its fruit on footstalks, hence called *pedunculata*. The latter has been raised to the dignity of a species by modern botanists, and it is said that the timber of the one is much more valuable than that of the other; but which is the superior, remains to be ascertained. While botanists assert that the *pedunculata* is the true British sort, an eminent builder denies that it is so, and has proved, in the course of his long experience, that the *robur*, or sessile-fruited one, of Linnæus, is the true naval oak. See **QUERCUS**.

OAK APPLE. The excrescences often observed growing upon the leaves and young stems of oaks, and which, when gilt, form so prominent a part of the decorations of the "Royal-oak day," are thus named, and are caused by the wounds made by several species of gall-flies when in the act of depositing their eggs. See **CYNIPIDÆ**.

OAT is the *Avena sativa* of Linnæus, one of our most useful agricultural plants. For the principal part of the food of the labouring classes in the northern parts of Britain, and for the food of horses in the south, one-fifth of the whole arable land in the three kingdoms is annually sown with this grain. Oats are generally sown on newly reclaimed land, or in regular rotations, usually follow wheat. The seed

time is during Lent, and the return varies from four to nine quarters per acre; general average about five quarters (forty bushels) from about five bushels per acre sown. In the north, the crop is reaped and bound in sheaves before it is carried to the barn. In the south, oats are mown, and, when sufficiently harvested, carried to the rick or barn loose.

OAT GRASS is the *Avena præcox* of Linnæus, a common British-grass frequent on waste ground.

OBESIA (Haworth). A genus of succulent gouty plants, natives of the Cape of Good Hope. The flowers are pentandrous, and the genus belongs to *Asclepiadææ*. Both plants and flowers are curious; they require to be potted in very light soil and lime rubbish, and mostly kept dry, except when flowering they may be allowed water more freely. They are propagated by cuttings, but not planted till the wound gets dry, otherwise they are apt to rot. This genus was separated from *Stapelia*.

OBSIDIAN. This mineral is found in two very distinct forms. The translucent obsidian, or *Lave citreuse obsidienne* of Hauy, is most frequently of a black colour; but some varieties are olive-green, and exhibit a beautiful silvery or golden opalescence. The island of Iceland produces the best specimens, but it occurs in most parts of the world. Transparent obsidian varies considerably in its colour, and consists principally of silica.

OCHNACEÆ. A small natural order, containing four genera, viz., *Ochna*, *Walkeria*, *Gomphia*, and *Castela*. They are trees or shrubs abounding with watery juices; their stems and branches are very smooth, leaves simple, alternate (in *Coriaria* alone opposite), entire, or toothed, penninerved, and furnished at the base with two stipules, which are deciduous, or sometimes absent. The inflorescence is subracemose, the flowers regular, united, and in general yellow. The calyx is formed of five sepals; the petals are equal, alternate with the sepals; the torus is turgid and discoid, bearing the carpels arranged round the median style; the stamens are five, alternate with the petals, and protruding from the margin of the disk; the filaments are free, bearing two-celled anthers, opening lengthways or by terminal pores. The germen consist of from five to ten carpels arranged in a whorl on the disk, with their styles combined, and forming a straight thread-like column that rises from the middle of the disk, and is persistent. The fruit consists of from ten to five, or by abortion fewer, carpels, which are sub-drupaceous, and one seeded.

The *Ochnaceæ* are bitter plants, and some of them are esteemed as tonics, such as *Walkeria serrata*, the leaves and roots of which, when steeped or boiled in milk or water, are administered as a stomachic, and are said to remove nausea and arrest vomiting. *Gomphia hecasperma* is astringent, and is found serviceable as an application to the sores caused in cattle by the punctures of insects. *Gomphia Jabotapita* has a fruit which is eatable, but rather too astringent to be agreeable; it likewise affords a bland oil, which is fit for salads and culinary purposes. The flowers of this plant, as well as those of other species, are very fragrant. *Castela Nicholsoni* is the goat-bush of Antigua; like its associates it is remarkable for its bitterness, and like them might be useful as a tonic.

There are several species of *Ochna* and its allies in our collections: they grow well in loam and moor-earth, and are propagated by cuttings.

OCHROMA (Sweet). A genus of West Indian trees, bearing monadelphous flowers, and belonging to the natural order *Bombacææ*. They grow freely in a mixture of loam and moor-earth, and are propagated by cuttings in the usual way.

OCTOMERIA (Dr. Brown). A genus of tropical herbaceous plants, belonging to *Orchidææ*. In our collections they are kept in pots of light sandy peat-earth, placed in cold frames during summer, but removed to the stove in winter.

OCULUS CHRISTI is a species of *Inula* so called. It is a hardy herbaceous perennial, and has a place in our flower borders. It bears yellow composite flowers.

OCYMUM (Linnæus) is a genus of sweet-smelling herbs, belonging to *Labiataæ*. Two of the species are cultivated as pot-herbs, under the name of sweet basil. They are raised from seed sowed annually in spring.

OCYPODA (Fabricius). A genus of short-tailed crabs (*Crustacea brachyura*), having the eyes large, and extending down their footstalks, instead of being terminal, as in the others. The tail of the males is very narrow, with the last joint elongate-triangular; that of the females is oval. The claws are of nearly equal size. These crabs, as their generic name implies, run with such great velocity, that it is asserted that a man on horseback has much difficulty in catching them; hence the specific name which was given to them by the old naturalists of cavaliers (*Eques*). During the day they keep in their burrows, which they excavate in the sand on the sea-shore. The species are chiefly tropical. The type is the *Cancer cursor* (Linnæus).

ODACANTHA (Paykull). A pretty genus of coleopterous insects, belonging to the family *Carabidææ*, and sub-family *Brachinidææ*, having the thorax long, narrow, and subcylindrical, the elytra truncate at the tips, and the tarsal joints entire. The type, and only British species of the genus, is the *O. melanura* (Fabricius), which is found in the fens of Cambridgeshire and Huntingdonshire.

ODICNEMUS—Thick-knee. A very peculiar genus of *Echassiers*, or stilt birds, having more resemblance to the plovers than to any other family; but still so distinct from it in structure, in haunts, and in manners, as to require a separate notice. Birds of the allied genera, and especially this genus, were most improperly classed as waders by the older systematists; for, instead of wading or otherwise seeking their food in the waters, they are found upon dry and sandy places, and upon such only. Africa and Australia are their head quarters, though some of them make excursions into light sandy places in temperate countries, and even pass the winter there, at least if it is very mild and open. They are characteristically birds of the desert, where that desert is open, and they studiously avoid the cover of woods and bushes. They thus form a distinct chapter in the history of nature; and their closest associates may be said to be the ostriches and the bustards, the last of which are found along with them in Africa; and the emeu takes the place of the ostrich in Australia, in which country there is no bird, hitherto discovered at least, which is properly typical of the bustards.

That the characters of the birds are well adapted to their very peculiar haunts will appear from the following enumeration: the bill is longer than the head, straight in its general line, and strongly made. It is a little depressed at the basal part, but com-

pressed toward the tip. The culmen of the upper mandible is elevated, and that of the lower forms an angle—a structure of bill which combines the two properties of lightness and strength. The nostrils open longitudinally in the middle of the length of the bill, and are in part protected by a horny plate. The legs are long and slender, with three toes to the front, but not even a rudiment of a hind toe. The three front toes are bordered with a membrane which unites them as far as the first joint; and this structure of foot possesses great elasticity, and also affords a firm plant or base to the bird in running. The enlargement of the knee, or rather of the ankle, from which the birds get their common name, is produced by the enlargement of the upper end of the tarsus, and the bones with which that is articulated. By this means a sort of cross lever power is given to the joint, which enables the bird to have great command over the tarsus, while the dry soil upon which it chiefly runs does not require, very great weight or general strength in that bone. The wings are of mean length, but they are rather pointed, the second feather being the longest. The tail is wedge-shaped, and the general form of all the organs of flight adapts the birds well for turning on the wing, or otherwise having a powerful command of the air.

Though this genus of birds were long confounded with the plovers, there is a remarkable distinction between them. Plovers, though they prefer open places and not woods, do not betake themselves absolutely to the desert; whereas the thick knees are always found on dry sands, and generally remote from the dwellings and the labours of man. They are exceedingly timid, and generally remain concealed during the day, so that one may pass near the places where they are without having the slightest chance of seeing them. When, however, the twilight closes in, the birds take advantage of its shade to come abroad on their feeding excursions. Their food consists of small ground animals, such as slugs, insects, and the more minute reptiles; all of which are, like themselves, abroad chiefly in the twilight. During the night they fly with rapidity, and utter a sharp plaintive cry, which is heard at a considerable distance. During the day the sound which they utter, when alarmed or otherwise excited, is in a deeper key, and heard at a much less distance. At these times they trust more to their legs than to their wings in seeking safety from enemies. There are very few animals of the same localities which can overtake them in running; the chief danger to which they are exposed is from birds of prey in the air, and by keeping the ground they can escape these better than if they were to take the wing. Birds of prey, which kill on the ground, could not descend with certainty upon a thick-knee if once alarmed, because that bird would be far enough out of the way before the enemy reached it; and as even those birds which prey on the ground, upon other birds or warm-blooded animals, must make a rush in the air in order to acquire the requisite impetus, it becomes impossible for them to make any thing of a bird which can run swiftly. Owing to these circumstances, the day flight of the thick-knees is always low and taken in short reaches. Their chief security upon the ground, however, consists in their being so like the colour of the sand, and squatting so closely upon it, that birds of prey cannot see them.

Their is a wide range in nature, but it is exceed-

ingly laborious; and therefore, besides their nocturnal activity in ranging from place to place, they are obliged to migrate with the seasons. They proceed northward about the month of April, and are driven south again by the autumnal rains. On their migrations they generally keep in flocks, resting during the day, and making their passage during the night with rapid wing, and apparently encouraging each other by their cries. When the nesting time comes the flocks break up, as is common with all birds which breed in comparatively bare pastures. Indeed this is so general a habit that it is necessary to be attended to by every one who wishes rightly to understand the nature of birds, and their general uses in the economy of creation. If the birds nestle where food is abundant for them, they are generally social in their nesting places. We have this exemplified in rooks, in herons, in house sparrows, and many others, especially of those birds of the rich tropical forests which load the trees with their nests. Of these social breeding birds it appears that the one excites the other, and the encouragement thus mutually given makes the labour proceed with greater celerity. But there is of course a limiting of this encouragement which bird can give to bird in the performance of labour; for, though the stimulus of a neighbour's voice and activity may prompt to labour, it cannot find a reward for that labour, unless such a reward is obtainable in the locality. We have often a very striking illustration of this in the case of the common rook. If, during the incubation, and especially after the young are beginning to break the shell, a severe frost should set in, and close the earth and the brooks for a succession of days, there is grievous lamentation among the dark inhabitants of the trees. The females cannot of course leave their charge, and thus the males are on the wing far and near in quest of a supply. This, which is always obtained with great labour under such circumstances, is often exceedingly scanty; and the complainings are sometimes painful to an experienced ear, as they express sufferings which are severely felt and cannot be relieved. When a kindly thaw comes, and the stores of the earth are again opened, the cawing of the rooks becomes exceedingly joyous; and no one would easily believe, if he had not carefully observed the fact, that notes so different in their sound and expression could be uttered by the same birds, at perhaps an interval of not more than two or three days.

Those birds which disperse at the pairing time are not subject to these casualties, because each has a sort of farm to itself, upon which no bird of the same species intrudes. There are not perhaps any two distinct species of birds which feed upon exactly the same sort of food; and therefore the dispersed birds are not so liable to suffer from other species as they would be from their own.

Birds which thus disperse in the breeding time rarely have any battles of gallantry among the males. Each pair betakes itself to its own station, where the two remain during the season in constant attendance upon each other. The female chooses some little hole sheltered by a tuft or bush, in which she deposits her eggs, which are usually two in number, generally of a greenish-yellow ground and spotted with brown. The young are carefully nursed for a time by the parent birds; and they are at least two or three years in acquiring the plumage of full maturity, which is gradually arrived at by a single yearly moult.

O. crepitans—Common Thick-Knee. This is the only bird of the genus which by any chance makes its appearance in any part of the British islands; and even there it is found only in the bare, dry, and warm places of the south and east, and is not found even in the midland counties. Norfolk, where there are many dry sandy plains, visited by rare birds more perhaps than any other part of the island, is so exclusively the abode of the few of this species which come to Britain, that the bird has been called the Norfolk plover. It is also called the stone plover and the stone curlew, though it cannot with propriety be referred to either of these genera. It is so exclusively a bird of the open plains that it is hardly seen in an inclosure, not apparently being fond of so much cover as that afforded by a single fence. It comes to us generally pretty early in April. Soon after this the cry of the male begins to be heard from the remote and bleak commons. It is rather loud, but harsh and grating, and resembles a sort of explosion. These birds have little time for nest-making, from the severe labour which the finding of food in such unproductive places requires from them. The sand or dry earth is merely a little levelled, and then the eggs are placed upon it. They are greyish in the ground, and mottled with red and brown. The time of incubation is described as extending to about a month. It is wholly performed by the female, for the male never sits on the eggs, but he watches very constantly beside the female during the day, to give warning of any danger that may present itself. In case of any such arriving, the female squats level with the surface of the ground; and the male shows himself, attempts to attract the enemy to a different quarter, and very generally succeeds in this. When he has succeeded in removing the danger to the necessary distance, he returns to his charge, and always does so by zigzags, of which no single line points directly to the nest.

The young birds, as is common with those of a species which do not construct formal nests, are thickly covered with down; and they are capable of using their bills and feet in finding their food, in which, however, they are assisted by the mother. The strong bills of these birds enable them readily to turn over small stones, and seize any little animals which may be below; and in this way they can find a supply of food in places where the surface does not present a single thing that a bird could eat. Morning and evening are their chief times of feeding, the latter especially, because it is the damper of the two, and the food of the thick-knees keeps longer out.

When the principal labours of the season are over, and the young able to procure for themselves the requisite supply of food, the birds again assemble in flocks, and they are a little bolder than they are during the breeding season. The hot sun always, however, reduces them to a state of languor, so that they squat down and remain still. But they never do this without having a watch set. If it is a single pair, in the breeding season, the male watches; but in the case of a flock, when the breeding season is over, there is always a regular sentry posted. As at this time each has nothing to do but find its own food, and provide for its own personal safety, they do not squat when the sentry gives the alarm, as the female does when she has her eggs to protect. They stand up, reconnoitre the danger, and each proceeds on its own way. In consequence of this watchfulness, these birds are much more rarely procured by

sportsmen than one would suppose from the readiness with which they can be seen on the bare places where they reside. Such, however, is the fact, and these birds are less frequently shot than many others which are in reality more rare.

They are birds which indicate a bleak and wild state of the country; and it is doubtful whether pasturing sheep has not some tendency to thin their numbers, because the sheep gradually bring a grassy sod over the surface, and this either prevents or conceals such animals as the birds would feed upon. The falling off of their numbers is therefore to be regarded as conclusive evidence of a country being in a state of improvement, while their increase is, on the other hand, a sign that it is falling into decay.

This last-mentioned circumstance not unfrequently renders the birds of a country a sort of progressive history of its condition at different times. The forms of wild nature, upon which man, in a climate like ours, breaks in when he cultivates, are the arid waste on the one hand, and the stagnant fen on the other, and the birds which are characteristic of such localities have gradually been becoming scarcer in England for many years past. The bustard, which was once by no means rare in the south, has become nearly extinct; and it is probable that the thick-knee is following it.

The thick-knee, though not a very heavy bird, is one of considerable dimensions. It is about seventeen inches in length, and twenty-five in the stretch of the wings. The bill is about two inches long, and the tarsi are between five and six, which raises the bird above the thin herbage of its haunts, and thus makes it appear much larger than it is in reality. Its neck is of course long to correspond with the length of the legs; for, in a bird which feeds upon the ground, those two parts are always adapted to each other. The upper parts are reddish-ash colour, with a longitudinal streak of brown down the middle of each feather. The sides of the head, both above and under the eye, are marked with white, which is found also on the chin, but not on the nape. The belly and thighs are also whitish; and the fore neck and breast are russet, with longitudinal streaks of brown. The coverts of the wings are brown, crossed by a band of white. The quills are black, the first with a white spot on the middle, and the second with a similar one on the inner web. The six middle tail feathers are barred with brown; the others are white with black bars; and they have all black tips, except the two middle ones. The bill is yellow at the tip, and black at the base. The irides of the eyes and the naked parts of the legs, which extend a considerable way above the tarsal joints, are also yellow.

O. magnirostris—Large-Billed Thick-Knee. This is an Australian species, having the upper parts mottled with ash colour, with red, and with brown, and a white band along the head bordered on each side by a black one. There is also a long black spot on each side of the neck; and the cheeks, chin, and throat are white. The nape and upper part of the neck grey with black spots. The wing coverts pure ash colour, crossed by a white band. Quills black, but with a white spot on the middle. The turn of the wing and the lower parts of the body very pure white, but with a streak of brown down the middle of each feather on the breast. The bill is longer, stouter, and more compressed than that of the European species, and wholly of a black colour. Though not

gaudy in its attire, the large-billed thick-knee is a very beautiful bird; but it is one, with the manners of which we have very little acquaintance. The wide plains of Australia, which are its chief haunts, have been very imperfectly explored; and when the weather is sufficiently dry for visiting them with ease and safety, they are so naked of herbage, that it is very difficult to get near so vigilant and active a bird as a thick-knee.

O. longipes—Long-Legged Thick-Knee is also an Australian species, remarkable for the length of its legs, and measuring twenty inches in length. The sides of the neck are brown spotted with white. The top of the head and the upper part of the neck are grey with longitudinal lines of brown. A space over the eyes, the throat, and the belly, are pure white; and the fore neck and breast white with longitudinal lines of black. The quills are black, and the middle tail feathers are grey with deeper bands of the same, while the lateral ones are black with white bars. The bill is black, and the naked parts of the feet brownish. This is a handsome bird as well as the former, though the extreme length of its legs give it rather a tottering appearance. But notwithstanding this, it is both a steady and a swift walker. The existence of two species of birds, which are so characteristic of desert countries, in Australia, is one strong evidence against the chance of that great island containing any considerable portion of fertile ground in the centre.

O. maculatus—Spotted Thick-Knee. This is an African, rather larger than the common species, but not so long as either of the Australians. Its length is about a foot and a half. The upper parts of it are russet-brown, spotted with blackish-brown, and the small coverts of the wings are of the same colour, but with white tips. A space round the eyes, the mustaches, the chin, and the throat are pure white. The neck and breast are russet with longitudinal black lines. The under parts are reddish-white, streaked with black. The bill is black at the point and yellow at the base, and the feet are yellow.

It will be seen from this description, that this African species much more resembles the common species which migrate from Africa to Europe, than it does the Australian ones; while they again have a nearer resemblance to each other. All the four species have, however, a very strong family likeness, more so than very many other birds with which we are acquainted; and there are no birds to which we can say that any of them is very nearly allied in its habits.

ODYNERUS (Latreille). A genus of hymenopterous insects, belonging to the family *Vespida*, or the wasps, and comprising the solitary species, or those which do not congregate and form a common nest. The abdomen is conic-ovate, and broadest at the base: and the terminal lobes of the mouth are short. The species are of smaller size than the common wasp, which, however, they resemble in colour, being black, varied with yellow. The females construct their nests in hot sand banks, the crevices of walls, or in rotten wood. These burrows are several inches deep, and of a cylindrical form; the entrance being defended, in some of the species at least, by a curved entrance, formed of fine kneaded sand, which the architect has brought up from the bottom of the nest. In the interior, and at the foot of this retreat, the female buries eight or ten caterpillars of the same species and size, but varying in the different

species; they are arranged in a spiral direction, and an egg is deposited in the midst, after which the mouth is closed. The young, when hatched, devours the inclosed caterpillars, which are just sufficient for its support; and then assumes the pupa state in a cocoon of a slender papyritious texture, which it has previously formed, and soon after becomes a perfect insect, and makes its escape. There are about twenty British species, but their specific characters are liable to considerable variation, so that the genus is very difficult of investigation. The type is the *Vespa muraria* (Linnæus). One of the largest species is the *Odynerus antilope*. A Memoir upon the habits of this species has been published in the Transactions of the Entomological Society, from which the following passage is extracted:—The writer noticed several specimens flying about, settling on a wall, and creeping into the holes which abounded in the rotten mortar. He observed one of the wasps fly down with something held beneath the whole length of its body, which it succeeded in carrying into its burrow. Another soon appeared, which he endeavoured to catch, in order to discover what the burthen consisted of; but the insect was too quick for him, and, with that solicitude which marks all the proceedings of these creatures in the constructing and provisioning their nests, it wheeled upwards to a considerable height, and made a circuit of several minutes' duration, and again attempted to reach the hole, which he again prevented by unsuccessfully attempting to knock it down with his handkerchief, when it soared away, and did not again return. He was, however, more fortunate with another, by allowing it to settle on the wall, and caught it as it was creeping with its prey into its burrow. This consisted of the green caterpillar of a *Crambus*, which is about the length of the insect's body, and which he noticed was held by the hind legs of the *Odynerus*, and consequently extended from the head to the extremity of the abdomen. Hence the *Odynerus* is essentially a fossorial hymenopterous insect (although belonging to a family containing the social tribes of wasps), furnishing its nest with larvæ; and yet neither the anterior nor the posterior legs are armed with those very remarkable spines which characterise those real fossorial nymenoptera which provision their nests. Here, therefore, we have another exception to the theory of M. Saint Fargeau, in addition to those observed by Mr. Shuckard, and described in his Memoir upon this subject in the first part of the Transactions of the Entomological Society.

CEDEMERIDÆ (Leach). A family of coleopterous insects, belonging to the section *Heteromera*, and tribe *Stenelytra*, of Latreille, having the body linear or oblong, the antennæ inserted near the eyes, the mandibles notched at the tips, the penultimate joint of the tarsi bilobed, and the maxillary palpi terminated by a large hatchet-shaped joint, the posterior thighs often greatly thickened in the males of some species, whence the name of the family, which means gouty-legged. The elytra are generally narrowed behind, and not meeting along the back. These insects are found in the perfect state upon flowers and trees, and amongst long grass. In their general appearance they have a considerable resemblance to the *Telephorida*. They are in general very active, and fly well. The family is but of small extent. The genera are, *Cedemera*, *Oncomera*, *Ischnomera*, *Nothus*, *Conopalpus*, all of which are British; and

Rhæbus, *Calopus*, *Sparedrus*, and *Dytillus*, which are foreign. The genus *Edemera*, as restricted by Stephens, consists of those species only which have the posterior femora greatly incrassated in the males, the antennæ long, and the elytra very much narrowed behind. The type of the genus is the *Edemera cærulea* (Linnaeus), a pretty little insect, found in the summer months upon various flowers.

CENANTHE (Linnaeus). A genus of herbaceous perennials, mostly natives of Europe, belonging to *Umbelliferae*. They are comparatively useless plants, and when grown in botanical collections are placed in water or on damp rich soil.

CENOTHERA (Linnaeus). A genus containing many species of annual, biennial, and perennial herbs, found in various parts of the world. They are ranged in the eighth class of Linnaeus, and in the natural order *Onagrarina*. Generic character: Calyx tubular, limb four-cleft; petals inserted into the calyx; stamens erect or declining; filaments awl-shaped; anthers incumbent; style filiform; stigma in four divisions; capsule nearly three-sided; seeds naked. The *Cenotheras* are in general fine flower-border plants. One of the most common in old gardens is that known by the vulgar name of *evening primrose*, from the flowers mostly expanding immediately after sunset. The roots of the *C. biennis* are esculent, and were once cultivated for the sake of their tubers, which in some measure might have stood in the stead of potatoes, but were superseded by the introduction of that much more valuable plant. The roots of this *Cenothera* were formerly eaten after dinner, as olives now are, being esteemed incentives to wine-drinking, and hence the generic name was changed from *Onagra*, the ass-food, to *Cenothera*, the wine-trap.

ÆSTRIDÆ (Leach). A very interesting family of dipterous insects, belonging to the section *Athericera*, having the mouth, in the winged state, quite, or almost entirely, obsolete, being replaced by three small tubercles, which can in nowise be applied as organs of nutrition. These insects have the appearance of large flies, with the body often very hairy, and ornamented with bands of various colours like the humble bees. The wings are very strong, and generally extended; the alulets are large, and conceal the halteres; the tarsi are terminated by two unguis and two pulvilli.

The habits of these insects are very peculiar, since their larvæ reside in the stomach, beneath the skin, or in the frontal sinus of various quadrupeds. We have, in the article *Bor*, given an account of the habits of those species of this family which attack the horse, and are known amongst farriers by that name, forming the genus *Gasterophilus* (Leach; *Gastrius*, Meigen); and have herein stated, that in the present article we should detail the habits of the other species.

It may, however, be observed in a general manner that these insects are rarely to be observed in the perfect state, although sufficiently common, and often very annoying to the animals which are subject to their attacks whilst larvæ. Each species of the family is confined to its own peculiar quadruped, and selects, for the deposition of its eggs, that particular spot which will be best adapted to the wants of the future larvæ. The ox, horse, ass, rein-deer, stag, antelope, camel, sheep, hare, and rabbit, have been ascertained to be subject to the attacks of these insects, which instil a

surprising degree of alarm into these animals when about to deposit their eggs. The larvæ, according to the situation in which they are found, may be called subcutaneous, cervical, and gastrical; the bots belonging to the last-named species. The larvæ are thick and fleshy, of a somewhat conical form, and destitute of legs; the body is composed of eleven segments, exclusive of the head, and furnished with minute tubercles or spines, often arranged in transverse series so as to be of service in progression. The chief organs of respiration are placed upon a scaly plate at the extremity of the body, which is the thickest part of the larva; their situation being, however, different in the gastrical species. Moreover the mouth of the subcutaneous larvæ is only composed of fleshy tubercles, whereas that of the gastrical species is armed with a pair of strong hooks—a variation of the structure dependent upon the variation of habit, and which requires that the larvæ placed in the midst of the stomach of an animal, and subject to the action of the food of such animal in its passage through its body, should be furnished with the means of holding itself firmly in its place. When full fed, these larvæ quit their retreats and descend to the earth, in which they pass the pupa state, the skins of the larvæ serving as the cocoon of the inclosed pupa.

The æstrus of the oxen, to which, in allusion to its habits, Latreille has applied the very appropriate generic name of *Hypoderma* (that is, living beneath the skin, or subcutaneous), is one of the most renowned of insects, its habits having been recorded by Virgil, in his third *Georgic*. Dryden gives the following translation of the passage in which the insect is referred to:—

About the Alburnian groves, with holly green,
Of winged insects mighty swarms are seen.
This flying plague (to mark its quality)
Æstros the Grecians call—*Asilus*, we—
A fierce loud buzzing breeze. Their stings draw blood,
And drive the cattle gadding through the wood;
Seized with unusual pains they loudly cry—

The claims of Dryden as a poet may be unquestionable, but he was no naturalist; and in these few lines may be seen examples of his merits and demerits. For the sake of his verse he has introduced the statement that the stings of this insect draw blood, and he has employed the popular but indefinite terms *breeze* and *gadding* (that is, flying from the *gad-fly*). Thus it would appear from this passage, that the insect in question was a *Tabanus*, which have the power of drawing blood with their powerful apparatus of lancets in the mouth. But Virgil was a naturalist as well as a poet, and he knew well that the effects which he has described were not caused by a *Tabanus*, but by an *Æstrus*. A more correct translation of the passage is given by Kirby and Spence:—

Through waving groves where Selo's torrent flows,
And where, Alborno, thy green ilex grows,
Myriads of insects flutter in the gloom,
(*Æstrus* in Greece, *Asilus* named at Rome)
Fierce and of cruel hum. By the dire sound,
Driven from the woods and shady glens around,
The universal herds in terror fly;
Their lowings shake the woods and shake the sky.

Now this is precisely the effect which the presence of a female æstrus (*Hypoderma*), buzzing about to deposit her eggs, has upon a herd of oxen. Terrified, with their tails in the air, or stretched out stiffly at full length, they gallop about the fields, resting only when they can make their way into a neighbouring

pool of water, where they are safe from the attacks of the insect. But the most curious part of the subject is, that this dread is merely instinctive. The œstrus inflicts no pain whilst in the act of depositing its egg, for it now seems decisively proved that the old account, that the ovipositor of the insect was capable of inflicting, and in fact inflicted, a wound for the reception of each egg, is unfounded, and that the eggs are merely glued by the out-stretched ovipositor of the female fly upon the hair of the back of the ox. No sooner is the larva hatched than, according to Mr. Bracy Clark, it burrows into the skin, and soon forms around itself a bump or protuberance upon the animal's back—a place, as Reaumur observes, where food is found in abundance, where it is protected from the weather, where it enjoys at all times an equal degree of warmth, and where it finally attains maturity. Reaumur has given a very detailed account of the habits of this insect; but admits that he never saw a female deposit her eggs, so that his supposition as to the parent fly piercing the skin of the ox does not rest upon direct observation, and is contradicted both by the texture of the ovipositor itself, and the statements of Mr. Clark. These larvæ are called warbles or wurmals, their habitations increasing in size according to the growth of the inclosed larvæ; the largest are nearly an inch and a half in diameter at the base, and about an inch high; they are scarcely perceptible externally during the winter, but attain their full size by the beginning of the summer. It is necessary that the tumour should have an orifice for the supply of air to the larva, and the situation of the spiracles is precisely that which is most admirably adapted for the nature of the habitation of the insect; had the spiracles been disposed along the sides of the body, as is their general situation, it would have been necessary that an open space should have been maintained around the body of the insect, but they are placed at the hinder extremity of the body, which is kept constantly applied to the orifice, which it exactly fits, and by this means not only is the aperture closed but a supply of air is maintained, and the head of the insect is placed at the greatest distance from the surface, and consequently most deeply into the flesh, where of course it obtains a great supply of food, which consists of pus, or matter secreted in consequence of the irritation produced by the insect. It is commonly upon the young cattle of two or three years old that they are found; they seldom attack old animals. The number of bumps upon an ox is various; in some not more than three or four are to be found, whilst in others as many as thirty or forty may be discovered. They are generally placed near the spine, but sometimes upon the thighs and shoulders; sometimes they are far apart, whilst occasionally several of them are so close as to touch each other. It must be evident, that if these larvæ fed upon the flesh of the beast the presence of so great a number must be attended with the greatest pain and suffering, but so far is this from being the case, that it would appear that they do the ox no material injury, and occasion none or but very little pain; indeed cattle most covered with bumps are not considered by the farmer as injured, the warbles being regarded as proof of the goodness of the animal, since these flies attack only young and healthy oxen. The tanners also prefer those hides which have the greatest number of warble holes in them, which are always the best and strongest.

The œstrus of the sheep which, from its larva inhabiting the frontal sinus of that animal, has been appropriately formed into the genus *Cephalemyia* by Latreille, is of a smaller size than the foregoing, being not more than five lines long, and of a greyish colour. The dread produced by the presence of this insect is exhibited in a different manner to that caused by the ox œstrus. The sheep shake their heads and strike the ground violently with their forelegs, or, running away, get into ruts, dry dusty spots, or gravel pits, where, crowding together, they hold their noses to the ground. The object of all this is to prevent the œstrus from depositing its eggs in the inner margin of the nostrils, whence the larvæ, when hatched, ascend into the head, feeding in the maxillary and frontal sinuses on the mucilage there produced. When full grown they fall through the nostrils, and assume the pupa state on the ground. The *œstrus trompe*, of Fabricius, inhabits the same situations in the rein-deer.

It appears certain, from numerous recent observations, either that there is a species of this family appropriated to man, or that, under certain circumstances, man is attacked by some of those insects which ordinarily infest quadrupeds. Gmelin, indeed, has introduced a species into the *Systema Naturæ*, under the name of *œstrus hominis*, with the observation, "Habitat larva in America Australi per sex menses sub cute hominum abdominali, turbetur profundius penetrando periculosa, adeo ut, fertur, lethalis; imago muscæ domesticæ magnitudine." The larva of this insect is found in South America, where, for a period of six months, it burrows beneath the skin of the abdomen of the inhabitants, penetrating deeper when disturbed, so as to become very dangerous, and, as it is said, to cause death, the imago being of the size of the domestic fly. Latreille also states, that M. De Humboldt noticed, in South America, Indians whose bellies were covered with small tumours, produced, as he supposed, by the larvæ of an œstrus, most probably belonging to the genus *Cuterebra* of Clerck. The same statement is also made in the *Essai sur la Géographie des Plantes*, p. 136, by Humboldt and Bonpland. See also the *Bulletin des Sciences Naturelles*, 1823; the 27th number of the *Magazine of Natural History*; the *Annales de la Société Entomologique de France* for 1833 (wherein is a valuable memoir by M. Geoffroy Saint Hilaire), and the *Medical Journal* for 1835; in which works various notices upon this subject are to be found, but of which want of space compels us to omit further notice.

The family is divided by Latreille as follows:—

- A. Proboscis distinct, but very small and retractile. genera *Cuterebra* and *Cephenemyia*.
- B. Proboscis wanting.
 - a. Palpi two. *Edemagena* (*œstrus tarandi*).
 - b. Palpi wanting. Genera *Hypoderma*, Latreille (*œstrus bovis*); *Gasterophilus*, Leach (*Gastrus*, Meig.; *œstrus*, Latreille; *œstrus Equi*); *Cephalemyia* (*œstrus ovis*).

OIL NUT is the *Hamiltonia oleifera* of Muhlberg, a genus belonging to *Santalaceæ*, formerly the *Pyrularia pubera* of Michaux.

OLACINÆÆ. A small natural order of plants, containing four genera and six species. The genera are *Olar*, *Spermazylon*, *Heisteria*, and *Ximelia*. The *Olacaceæ*, as this order is called by some authors, are arborescent plants, with alternate entire simple leaves; sometimes the foliage is abortive, and the stipules are

always absent. The inflorescence is axillary, and the flowers small, unsymmetrical and united, or, by abortion, polygamous. The calyx (?) is small, entire, or slightly toothed, and often becoming enlarged or fleshy. The corolla of from four to six hypogynous petals, which are separate or connected in pairs through the intervention of the filaments. The stamens are definite, part being sterile in the form of hair-like nectarines, opposite or attached to the petals, and coherent with them by the filaments. The germen is free, and one-celled. Style filiform, and stigmas from three to four. The fruit is sub-drupaceous, indehiscent, and often invested by the persistent fleshy calyx or involucre. One-celled and one-seeded.

Of the properties of these plants there is very little known: some are esculent, and all, as far as experience goes, innocuous. *Olea Zeylanica* is used in Ceylon as a pot-herb, and also as a salad: it is there called *mala-hola*, which signifies salad-tree, whence its generic name, which is more probably a corruption of *hola* than a misapplication of *ola*.

The fruit of *Ximenia Americana* is eatable. It is about the size of a pigeon's egg, of a yellow colour, and has a sweetish subacid flavour. *Heistera coccinea* is the "bois perdrix" of the French colonists in Martinique, and it affords the partridge-wood of European cabinet-makers.

Decandolle, Lindley, and other botanists, are not decided whether the genera associated under this title really deserve to be made a separate order, as all of them may be fairly referred to other and well-established orders. They are all increased by cuttings.

OLEINÆ, or OLEACEÆ. A generally cultivated natural order of trees and shrubs, containing eleven genera and one hundred and twenty-four species. The genera are: *Fraxinus*, *Ornus*, *Chionanthus*, *Milingtonia*, *Linociera*, *Fontanesia*, *Notekea*, *Olea*, *Phillyrea*, *Ligustrum*, and *Syringa*.

The *Oleaceæ* have aqueous juices, erect or climbing stems; their leaves are opposite, petiolate, simple, seldom ternate or pinnate, and destitute of stipules; the inflorescence is paniculate, and the flowers regular and united, or sometimes, by abortion, polygamous; the calyx is free, disk absent, corolla hypogynous; the stamens, two in number, are hypogynous when the corolla is absent, epipetalous when it is present, being exerted from its tube, alternate with its lateral lobes, or, when tetrapetalous, connecting the lateral petals in pairs; the filaments are free, anthers two-celled, opening laterally by longitudinal clefts; the fruit is drupaceous, baccate, or capsular; the seeds erect or pendulous; and the albumen fleshy or horny.

Among the most important genera for ornament are the lilac, phillyreas, and different varieties of ash; and of the most useful is the olive, the fruit of which abounds in a bland fixed oil. This oil is expressed from the fleshy pericarp, the olive being one of the several, yet few, exceptions to the general rule of fixed oils, being obtained from seeds alone. The olive grows freely in the south of Europe; and, although it does occasionally bear fruit in this country, the crops would be too scanty and uncertain to allow an extensive cultivation. Our chief supplies of olive oil are obtained from Italy, especially from Florence and Lucca; but that from Provence is of superior quality. In Spain and Italy this oil supersedes the use of butter; hence its consumption in those countries

is far greater than amongst us, our annual imports averaging only a little more than two million gallons. Besides the oil, the unripe fruit of the olive is pickled and eaten on the Continent to provoke an appetite. Here olives are taken after dinner to cleanse the mouth, so that the flavour of the wine may be the more enjoyed.

Ornus Europæa is the manna-ash. This and the other species yield that peculiar saccharine cathartic known in medicine under the name of manna; chiefly brought from Calabria, where the trees abound.

The plants of this order are chiefly increased by grafting or budding, and sometimes by layers and cuttings.

OLIVE WOOD is the *Elæodendron orientalis* of Jacquin: East Indian and Australian trees and shrubs, belonging to *Celastrinæ*.

OMALIUM (Gravenhorst). A small genus of rove beetles (*Brachelytra*), forming the type of the sub-family Omalides (*Omalida*, MacLeay). See BRACHELYTRA.

OMASEUS (Zeigler). A genus of coleopterous insects, belonging to the family *Carabidæ*, and sub-family *Harpalidæ*, the true type of which is the *Carabus melanarius*, a very common English species, in which the wings are rudimental, the thorax with the hinder angles acute, margins incrassated, mandibles striated, body oblong, depressed, and anterior tarsi with three dilated joints in the males. There are eight or ten British species, found chiefly under stones, moss, &c.

OMOPHRON (Latreille; *Scolytus*, Fabricius). A small but very interesting genus of coleopterous insects belonging to the family *Carabidæ*, but differing from the majority of those insects in the form of the body, which is nearly orbicular and convex above, the thorax, very short, and the scutellum not visible. The basal joint of the tarsi is alone dilated in the males. The species are but few in number, and frequent the margins of water in Europe, North America, Egypt, and the Cape of Good Hope. In this respect, as well as in the form of the body and of the larva, this genus is regarded as the connecting link between the hydradephagous and geodephagous predaceous beetles.

OMPHALEA (Linnæus). A genus of West Indian trees, belonging to the natural order *Euphorbiaceæ*. Generic character: flowers in panicles and monœcious; calyx in four parts, divisions concave and obtuse; corolla none; stamens, the filaments dilated above; anthers two-celled; style thick; stigma somewhat trilobed; fruit of three berries; seeds hemispherical. This is a stove exotic, and thrives in light soil, and may be increased by cuttings.

OMPHALOIDES (Lehmann). A genus of annual and perennial herbs, having pentandrous flowers, and belonging to *Boraginæ*. The Venus navelwort is a common flower-border annual seen in every garden.

ONAGRARIA. A natural order, containing fourteen genera and one hundred and forty-six species, already described and named. This, says Lindley, is a well-defined order, generally known by its pollen cohering, by a sort of filamentous substance, an inferior polyspermous ovary, a four-sepaled, four-petaled flower, with a definite number of stamens and a single style. They are all innocuous plants, but more celebrated for the beauty of their flowers than for their medical or economical importance.

Many of them, such as the *Fuchsia*, *Epilobium*, *Gaura*, *Clarkia*, and *Lopezia*, are highly ornamental plants. *Montinia acris*, which is remarkable for having albuminous seeds, likewise deviates from the other genera in having an acrid fruit. Of the *Epilobia*, or willow herbs, the *E.* or *Chamnerion angustifolium* is said to produce a kind of intoxication, or to stupify those who drink a decoction of the stems and leaves; and hence perhaps the reason why it is added by the Kamschatdales to "enrich the spirit" they prepare from the cowparsnep. The pith when dried becomes sweet, and the same people brew from it a kind of ale, and also procure their vinegar. The young shoots of this and other species are also eatable, when dressed in the same manner as asparagus. The *Epilobia* are valuable for shrubberies, growing in the shade, and remain unhurt among the smoke of large towns. The leaves of *Jussieuia Peruviana* are esteemed in America for making good emollient poultices. *Circæa*, the enchanter's nightshade, is a common British plant, and though it bears an ominous name, being named after the famous enchantress Circe, it is an entirely innocuous plant. All the genera are increased by cuttings or seeds.

ONCIDIUM (Swartz). A beautiful genus of South American perennial herbs, bearing gynandrous flowers, and belonging to the natural order *Orchideæ*. This, like many of its congeners, is found growing on the stems of trees in thick shady and damp woods of Brazil and other parts of South America. In our collections the species are grown in moist stoves kept at a high temperature; and, to imitate their natural habitat, are fixed to a rugged branch of a tree among moss, and outer shells of the cocoa-nut nailed round to form a bed for the roots. They are increased by division of the roots.

ONION is the *Allium cepa* of Linnæus, a well-known culinary vegetable. Garlic, and onions of various kinds, were highly esteemed in Egypt, and, according to Hasselquist, not without reason. He conjectures that the *A. cepa*, which is still used in that country in amazing quantities, and forms a most delicious food, is one of the species of onion after which the Israelites longed when in the wilderness. He says—"Whoever has tasted onions in Egypt will allow that none can be had better in any part of the universe. Here they are sweet, in other countries they are nauseous and strong; here they are soft, whereas in the northern and other parts they are hard, and the coats so compact that they are difficult of digestion. Hence they cannot be eaten in any place with less prejudice and more satisfaction than in Egypt."

It was probably an assumption of austerity and show of self-denial which caused the Egyptian priests to abstain from the use of onions as food, and this subsequently led to the superstitious reverence with which, by the bulk of the people, they were regarded. Lucian, when giving an account of the different deities worshipped in Egypt, states that the inhabitants of "Peluseum adore the onion." The Egyptians, indeed, were commonly reproached for swearing by the onions and leeks in their gardens; for Pliny says—"Allium cepasque inter Deos in jure jurando habet Egyptus," an absurdity which did not escape the scourge of Juvenal:—

"O sanctas gentes quibus hæc nascuntur in hortis
Numina."

"Religious nation, sure, and blest abodes,
Where every garden is o'er-run with gods."

But, while some of the people did not dare to eat leeks, garlic, or onions, for fear of injuring their gods, others fed on them with enthusiasm, excited by the zest of appetite, if not by religious zeal, if we may judge from the distich which declares that

"Such savoury deities must sure be good,
Which serve at once for worship and for food."

ONISCUS (Linnæus). A genus of apterous insects, belonging to the class *Crustacea*, order *Isopoda*, and forming the type of the family *Oniscidæ*, in which the body is of an oval or hemispherical form, with four antennæ, the intermediate pair being very small, and only two-jointed. The abdomen is six-jointed, and very short, with two or four terminal styles, and without any lateral swimming plates; some of the species of this family are aquatic, whilst others are terrestrial, and the modifications which the organs of respiration undergo in those different species are very interesting. The restricted genus *Oniscus*, of modern authors, comprises only terrestrial species, being confounded with the *Glomeris marginata*, under the common name of wood-lice. They have eight joints in the lateral antennæ, the base of which is not exposed; the two external appendages of the tail are much larger than the two interior. They frequent dark and retired situations, such as cellars, caves, the cracks of walls, &c. They are also fond of burrowing into rotten window-sashes, beams, decayed trees, &c. They feed upon vegetable and animal matter in a state of decay, appearing abroad only in rainy or damp weather. They creep slowly, and are easily alarmed; the eggs are enclosed in a pectoral pouch, in which the young are hatched, these, at their birth, are deficient, wanting one segment and a pair of legs, which they afterwards acquire. The typical species *Oniscus asellus*, Linnæus, is very abundant, and commonly called pigs'-louse, wood-louse, &c. It was formerly employed in medicine, and was supposed to cure agues, consumptions, &c.; but it has now, like many other similar medicines, been expunged from the Pharmacopœia. The writer has observed, that the young of the common species, whilst very small, and of a white colour, frequents the nest of the brown garden ant, with which it lives in perfect harmony. Mr. Knapp has noticed the same thing in the nest of *Formica flava*. He says, "some of these ant-hills contained multitudes of the young of the wood-louse, inhabiting with perfect familiarity the same compartments as the ants, crawling about with great activity with them, and perfectly domesticated with each other; they were small and white, but the constant vibration of their antennæ, and the alacrity of their motions, manifested a healthy vigour, although the ants at the same time were in a torpid state."—Journal of a Naturalist, p. 304.

ONOBRYCHIS (Tournefort). A genus of herbaceous plants, chiefly natives of Europe. The flowers are diadelphous, and belong to the natural order *Leguminosæ*. Several of the species were ranked as hedysarums by Linnæus, and of them the type of the genus is the well-known agricultural plant called saintfoin. On chalky loams this plant is a useful one to the farmer when the season for making the crop into hay is favourable. It is fit for the sithe as soon as any of the clovers (except, perhaps, the scarlet trefoil), and its hay is prized above that of all other plants; but one shower of rain upon it, after it is cut and withered, spoils it entirely, so that it is not so generally cultivated as it otherwise would be,

more especially since our summers have been so very unsettled. Saintfoin hay is preferred for fattening deer by the park-keepers, and always commands the highest price in the hay-markets. It is also a useful pasture plant, particularly in dry summers, its deep-running root reaching moisture when other shallow-rooting plants are burnt up. Saintfoin should not be grazed late in the spring, lest the points of the strongest shoots be nibbled off.

ONONIS (Linnaeus). An extensive genus of annual and perennial trailing herbs and undershrubs, natives of Europe and Southern Africa. The flowers are beautiful, and monadelphous and bearing pods belong to *Leguminosæ*. One, the *O. spinosa*, is a British plant, and known by the name of Rest-harrow. None are in cultivation.

ONOPORDIUM (Linnaeus). A genus of European herbs, chiefly biennials, belonging to *Compositæ*, and in English lists are called cotton-thistle. *O. acanthium* is a British plant, which, together with some of the continental species, being stately plants, are admitted into our shrubberies.

ONOSMA (Linnaeus). A genus of half-hardy herbaceous perennials, bearing pentandrous flowers, and belonging to *Boraginæ*. Generic character: calyx in five parts; corolla tubular or bell-shaped; stamens included or equal with the corolla; anthers broad at the base; nuts oval and stony. These are handsome plants, and thrive in rich light soil; a few should be kept in pots, and placed in a frame during hard frost.

ONTHOPHAGUS (Latreille). A genus of lamellicorn beetles of very great extent, belonging to the family *Scarabeidæ*, distinguished by wanting a scutellum, as well as the third joint of the labial palpi; the legs are short and robust, with the tibiae somewhat triangular; the body is short, with the thorax thick, broader than long, orbicular or semicircular, and incised in front. The head, and often the thorax, are armed with horns or spines in the males. The species are of small size, and are found in the excrement of various animals. Their colours are often obscure. The *Scarabeus taurus*, Linnaeus, belongs to this genus, and is remarkable for the two strong curved horns on the head of the male, which resemble those of a bull. A single individual of this species has been found in the New Forest in Hants. There are ten British species.

ONYX. This is one of the forms of the common calcedony, and it is usually marked by an alternation of white, black, and dark brown layers. The ancients attributed wonderful properties to the onyx stone, and imagined that it would cure many diseases if worn on the finger, and on this account it sometimes fetched enormous sums.

OPAL. There are few minerals that have been more highly valued than this gem. The principal colour of the common opal is white and semi-transparent, with a brilliant lustre. The fire opal on the contrary is of a hyacinth-red colour, and both kinds are found in every part of the world. Wood opal is the only other species of this mineral that is usefully employed. It varies considerably in its colour, and, as its name implies, much resembles the branches of trees. It is principally found in Hungary, and, when cut into plates, is employed by the jeweller and lapidary.

OPATRUM (Fabricius). A genus of small heteromorous beetles, generally found in sand-pits, and belonging to the family *Tenebrionidæ*. The *Silpha*

sabulosa, Linnaeus, is the type. The body is sub-depressed, the antennæ short, with the terminal joints broader and transverse, the anterior tibiae sub-triangular. These insects are of black or obscure colours, and feign death when alarmed.

OPERCULARIÆ. A small natural order of plants comprising only two genera, viz., *Opercularia* and *Cryptospermum*; exotic weeds nearly allied to *Rubiaceæ* and *Valerianææ*.

OPETIORHYNCHUS. A genus of American birds, with anisodactylic feet, resembling the bee-eaters in some of their habits, but differing greatly from them in others. Their characters are: the bill longer than the head, straight, or but slightly curved, and but very slender, depressed at the basal part, but compressed at the tip, which is awl-shaped; they are not wild and solitary birds, and one rarely meets with them in any other situation than in pairs. They fly about houses, and often enter them, and they are seldom met with in the depth of the close forest. Their wings are short, and their tail is also short, wedge-shaped, and feeble. They are therefore not well adapted for long flights; but they stand high on the legs, and thus are well adapted for walking. Their nests are constructed something in the form of ovens, for which reason they have been termed oven-birds by some naturalists. These nests are indiscriminately placed against large branches of trees, the corners of windows, gate-posts, and various other means of support. The nest is of a hemispherical shape, formed entirely of soft mud by the labour of the birds. The interior of this nest is about six inches in diameter, and divided in the middle by a partition, through which an opening is left for the passage of the bird from the one chamber to the other. It is understood that the inner chamber is the one in which the incubation is carried on, and it is bedded with soft vegetable matter, in order that it may better answer this purpose. The eggs are four in number, nearly white in the ground, and marked with small reddish dots. Some of the species construct nests; and it is astonishing that so small a bird should construct this kind of nest, and make it so firm in its texture as that it will bear to be agitated by the rude winds at the end of a flexible branch. In order to give this consistency to the large pendent nests, vegetable fibres are intermixed with the other materials, and very firmly worked or matted together. The large nests are usually divided into a number of chambers to which there are various openings. The partitions which divide these chambers from each other, answer another important purpose besides mere convenience to the inmates. They bind the structure together, much in the same way as a house is bound together by the wooden framing of the floors and partitions. We cannot suppose that the birds have the slightest tendency to contrive those partitions for the strengthening of their fabrics; but still this does not lessen the extraordinary fact, that instinct should be able to accomplish, without any contrivance, far more nice, and even far more scientific structures, than man can frame, notwithstanding the use of observation, and reason, and the help of scientific investigation. But we must not wonder at this; for there is not a single part in the structure of any animal, or any plant, or in the distribution of any one portion of mineral nature, which does not, when properly improved, tend to lay the whole fabric of man's boasted science in the dust, and send him to school

to the very humblest thing in the whole operations of nature. But while we are thus humbled in the unjustifiable part of our vanity, by what appears to us as a spontaneous evolvment without design, so greatly excelling all that we can possibly design, there is still room for us to feel the warmest gratitude for the goodness of our Creator in placing us in that situation which we do occupy. All the other creatures, how curiously soever they may carry on their operations, are still ignorant of the fact, that those operations are curious, and they may truly be said to have "no part or lot in the matter," and nothing like intellectual pleasure when their labour is performed. We bear our part, and we enjoy the pleasure; and, therefore, this is more than a compensation to us for those failures which naturally, and almost necessarily occur in our peculiar kind of practice, though of course they are altogether avoided by those creatures which entirely depend on a higher power.

In the curious nests of some species of these very interesting birds, only one of the apartments which are partitioned off is destined for the eggs and the hatching of the brood. The other apartments are not, however, without their use; and there is something very pleasing in contemplating the use to which they are applied. They are a sort of play rooms for the young birds, in which they are enabled to exercise their limbs, which are with them by far the most essential organs of motion, so as to have acquired the requisite degree of strength, before they have the accommodations of the maternal dwelling.

Some provisions made in this way by the birds, and even by insects, so far exceed what human beings can do, that did we not consider from whom they originate, they would be among the especial wonders of the world, all wonderful as it is. But when we reflect on the natural laws according to which the whole system of nature is carried on, we cease to wonder at the matchless superiority which they display. These are all direct results of a Wisdom which is complete in everything which respects the materials, the structure, and the office which that structure is to serve, whereas we are originally in total ignorance upon all these points; and though we learn ever so long, and with ever so much diligence, still our learning reaches only a very little way, how far from perfection we cannot know in any case, but with most, or, indeed, with all of us, it may be said to be but a mere beginning. There is no department of nature in which we may receive lessons at once calculated to correct that self-sufficiency which tends to make us rest contented in our ignorance, and to produce a thirst for knowing more, than the study of birds, which are so much before our eyes, and which perform such singular labours. The present genus, from its familiarity, is one well calculated for the instruction of those who inhabit the countries that it frequents. Three principal species are mentioned, all American, and not spending the summer, at least, in the very hottest parts of that continent. Their names and appearances are as follow.

O. rufus is a native of the southern parts of the United States. The upper parts are russet-brown, and the top and sides of the head dark brown. Over the eyes there is a yellowish-brown streak; and this also is the colour of the upper side of the wings, which are, however, traversed by a band of russet. The quills are reddish-brown, and so are the flanks. The under part is whitish, the bill brown on the

upper part and whitish on the under, and the feet black. In its plumage this is but a homely bird; but its appearance is pleasing.

O. annumbi. This species is a little larger than the North American one, being seven inches and a half in length. It is reddish-brown, spotted with black on the upper part, bright brown on the forehead, and deeper brown on the top of the head and upper part of the neck. The coverts of the wings and the smaller quills are clear brown, and the primary quills bright reddish-brown. The sides of the head are whitish, with a brown streak behind the eye. The throat is white, with a brown streak descending from each angle of the gape, the under part mottled with brown and white. The under coverts of the wings shining white, clouded with reddish. The lateral feathers of the tail are black with brown borders, and a white spot upon the tip of each. The two middle ones are clear brown, the bill reddish-brown, and the feet olive. In its colour this is a much more handsomely-formed species than the last; and it is described as being exceedingly numerous in some of the provinces along the river of Paraguay and its affluents.

O. ruber is also a species of Paraguay, and larger than the preceding one, measuring fully eight inches in length. It is also the most gaily coloured of the whole. The upper parts are russet-brown; the sides of the head brown; the wing coverts carmine-red; the larger coverts deeper red with blackish tips; and the quills reddish-purple. The under parts are white, forming a fine contrast with the bright colours of the upper parts. The feathers on the head and upper part of the neck are stiff, with the shafts projecting a little beyond the webs in small points, which give these parts something of the appearance of being composed of a mixture of feathers and bristles. The bill is blackish above and whitish on the under side, and the feet are greenish-brown.

With the exception of colour, and partially also in size, all the species of these birds resemble each other very closely; while the peculiarity of their manners points them out as a well-defined and strongly-marked genus.

OPHICEPHALUS—Serpent Head. A genus of spinous-finned fishes, with cells on the bones of the pharynx fitted for retaining water, so that the fishes can travel for considerable distances and climb up trees, still retaining enough of water to moisten their gills. Their bodies are lengthened and nearly cylindrical. Their muzzle is short and blunt, and their head is depressed and covered with large polygonal plates, resembling the scales on the heads of serpents, from which they have obtained their name. They have six rays in the gills; their dorsal fin extends their whole length. Their anal fin is also long, and the termination of the caudal is rounded off. They are chiefly found in the fresh waters of India, where some of the species grow to the length of four feet, while others do not exceed ten inches in length. The small ones are often exhibited as curiosities in India, from the length of time that they can creep about on dry ground, and the heights to which they can climb. The species are rather numerous, and they are highly characteristic of countries where fishes' food is abundant during the floods, and where the fishes themselves require to follow the ebbing off of the waters when the dry season sets in.

OPHIDIA, from *OPHIS*, a snake. The fourth order into which Cuvier divides the class of reptiles,

and which includes all the serpents and snakes, whatever be their nature or their modes of life. They are animals of obscure habits, and principally confined to the warmer climates of the world ; and they are the only vertebrated animals which have a distinct apparatus for infusing venom into wounds, and thereby occasioning the death of most animals which they bite, and severe pain to all animals. Their general relations will be pointed out in the articles REPTILE and SERPENT.

OPHIDIUM. A genus of fishes, belonging to the soft-finned ones, which are without ventral fins, and have the body eel-shaped. The body is lengthened and compressed, so that it has been compared to a sword in shape. The scales are very small, and closely embedded in the skin. But though in their general form they very much resemble the eels, yet they differ considerably from them in the structure of their gills, which are open, so that the fishes have more free motion in the water, and cannot live so long when removed from it. The species best known are natives of the Mediterranean. One small species is flesh-coloured, with small black spots on the dorsal and anal fins. Another is larger, of a brown colour, without any spots on the fins, which last one is reckoned very wholesome food. Others are found on the shores of Brazil and in the South Sea, in the last of which there is one of large dimensions, rose-coloured in the ground, and spotted with brown. All these have appendages to the under jaw, of greater or less length in the different species ; but there are others which want these appendages, and also have the dorsal fin nearly obliterated. The largest one is found near the coast of New Zealand, six feet in length : they are much esteemed as food. Their history is very obscure.

OPHION (Fabricius). A genus of parasitic hymenopterous insects, belonging to the family *Ichneumonidae*, having the ovipositor of the females scarcely exerted, the abdomen compressed and sickle-shaped, the antennæ filiform or setaceous, the second cubital cell of the upper wings is very small or obsolete. The type of the genus is the *Ichneumon luteus*, Linnæus. It is of a reddish-yellow colour, and about three-fourths of an inch long. It often flies into lighted rooms at night. The female deposits her eggs upon the caterpillar of the puss-moth (*Cerura vinula*), being attached at the extremity of a long and slender foot-stalk. When hatched they reside outside the body of the caterpillar, with the extremity of their bodies placed in the pellicle of the egg, from which they have burst forth. After the caterpillar has spun its cocoon, it is so much exhausted by their attacks, that it soon dies ; the parasites then spin their own cocoons within the cocoon of the dead caterpillar, and soon afterwards make their appearance in the winged state. Mr. Curtis observes respecting this insect, " It has struck me as very remarkable, that one often can obtain only one sex of *Ophion* from an infested larva, although a considerable number may be hatched ; having observed this several times, it can scarcely be accidental. I am therefore inclined to think that one sex appears before the other, and that the eggs of each are deposited separately in different caterpillars."—British Entomology, No. 600.

OPHIOPOGON (Ker). A genus of two curious herbaceous plants from China, belonging to *Smilacææ*. Generic character : calyx corolla-like, half superior, limb six-cleft, spreading ; stamens above the germen,

filaments short, anthers erect, long, heart-shaped ; style three-sided ; stigma three-lobed ; berry three-seeded. These plants grow freely in any light rich soil, and are increased by dividing the root.

OPHIORHIZA (Linnæus). An East Indian undershrub, called in that country *Mungos*, and in China *Chyn-len*, bearing pentandrious flowers, and belonging to *Rubiaceæ*. Its rhizoma or underground stem is called by druggists *snakeroot*, and is a very strong bitter, highly valued in China. In our stoves the plants are grown in loamy moor-earth, and are increased by cuttings.

OPHRYS (Linnæus). A genus of tuberous-rooted herbs, chiefly natives of European meadows, belonging to the class *Gynandria*, and natural order *Orchideæ*. The curious forms of these flowers have gained for them provincial names, by which in common language they are known. One is the bee, another the drone, one is the fly, another the spider, ophrys, &c. The flowers are more curious than showy, but are all admirable, whether in their wild state or in botanical collections. The best artificial soil for them is a mixture of chalk, loam, and moor-earth, but when so cultivated, they require protection as well from long continued rain as from hard frost.

OPILO (Latreille ; Noroxus, Fabricius). A genus of coleopterous insects, belonging to the family *Cleridæ*, having all the palpi terminated by a large hatchet-shaped joint, the antennæ gradually thickened to the tips, the intermediate joints being of a conical form. These are pretty insects, generally of considerable rarity, one species only being found in this country (*Attelabus mollis*, Linnæus), which is met with under the bark of old trees where the larva has fed upon other wood-boring larvæ.

OPUNTIA (Haworth). A genus of succulent undershrubs, commonly called Indian fig from the form of their fruit. The flowers are icosaandrous, and the genus belongs to the natural order to which it gives a title, viz.

OPUNTIACEÆ, or CACTEÆ. A natural order containing nine genera, and one hundred and fifty-six species. They are all succulent plants, destitute for the most part of leaves, the place of which is supplied by fleshy stems of the most grotesque shape : some angular, and attaining the height of thirty feet ; others roundish, covered with stiff spines like the hedgehog, and not exceeding the height of a few inches. Their flowers are in many cases large and remarkably specious, varying from pure white to rich scarlet and purple, through all the intermediate gradations of colour. The species are chiefly natives of the hottest and driest parts of the tropics, and are cultivated with little care in pots filled with lime rubbish in a dry stove. Their fruit is fleshy and watery, and generally insipid, but it is eaten in their native countries for the sake of its refreshing moisture and coolness. Two species of *Opuntia* are hardy in Britain. The order consists of two tribes, namely, *Opuntiaceæ* and *Rhipsalidæ*. The first contains *Mammillaria*, *Cactus*, *Melocactus*, *Echinocactus*, *Cereus*, *Epiphyllum*, *Opuntia*, and *Pereskia* ; the second comprises the genus *Rhipsalis*, Lindley. They are all easily increased by suckers, offsets, or cuttings, the moist base of the cutting being first allowed to become dry before placing in the soil.

ORACHE is the *Atriplex hortensis*, a native of Tartary, and belonging to the natural order *Chenopodeæ*. It was formerly cultivated in our gardens

as a spinacious vegetable, but is now very much out of repute.

ORANGE TREE is the *Citrus aurantium* of Linnæus, an Asiatic fruit, and long cultivated in our greenhouses, but much more for the beauty of the foliage and fragrance of their flowers than for their fruit. The orange is a species or variety of a very numerous family, including the lime (whence perhaps the whole have sprung), lemon, citron, orange, and the shaddock, of all of which there are innumerable varieties. The lime is the smallest, and found wild in the jungles of India. The shaddock is the largest, but much inferior to the orange. The lemon is most used for medical and culinary purposes. The *C. Paradisi* is a variety called the "forbidden fruit," from its size and beauty, but is inferior to the best oranges. We have the following imported sorts, viz., the common sweet, the China, the Majorca, the Nice, the Genoa, the Portugal, the Malta or blood-fruited, the St. Michael's, and the Oporto or pipless pot oranges. There is also the Seville orange of inferior quality for the table, but they are extensively used for other purposes. We have orangeries in this country, in which the fruit is brought to the greatest perfection; but the imported fruit, being so plentiful and cheap, renders glass covered buildings less necessary for the culture of oranges.

ORCHIDÆ. One of the most natural and well-defined orders in the vegetable kingdom. In the latest published lists there are above one hundred and fifteen genera, and four hundred and thirty species enumerated, to which we are every day adding new genera and many new species, chiefly from South America. The *Orchidæ* are chiefly perennial and herbaceous plants, some few only being suffrutescent, and in many the stem is obsolete; but to the crown of the root, one, two, or more fleshy tubers are attached, which contain the buds that are to form the plants of the succeeding year; in others the tubers are bundled or composed of thick fibres; in others again the above-ground stem is enlarged and succulent; many of them are epiphytic, as the *Epidendrea* and *Vanilla*.

The leaves are simple and entire, alternate, either sheathing or articulated, with striated veins, and occasionally degenerating into scales.

The perigonium consists of six pieces, mostly petaloid, and arranged in two series. The sepals of the calyx are in general similar to each other, the odd one being uppermost; the petals of the corolla vary in form; the upper petal, which by the twisting of the ovarium becomes apparently the lower, is called the *lip* (labellum), as the two lower sepals, which become from the same cause uppermost, are named the *helmet* (galea). The lip, which is often lobed and assumes a great variety of forms, likened to men, monkeys, flies, butterflies, bees, &c., has been called by some persons the nectary. The stamens are three in number, becoming by abortion two or one, and, united with the pistil, forming a fleshy column, called the *gynosteme*, which surmounts the ovary; and hence these plants have been termed *epigynous* by Jussieu, and *gynandrous* by Linnæus. On the apex of the gynosteme there is found, in the *Orchidæ*, a two-celled anther; and on either side an eminence (*staminoida*) marking the abortion of the other two, which remain in a rudimentary state in all the type named, from orchis, the *Orchidæ*, and which are placed by Linnæus in his order *Monandria* of the twentieth class.

In front of the single anther in *Orchis*, and rather before and between the two anthers in *Cypripedium*, there is a secreting cavity, which is the naked stigma of the pistil, the other part of which is blended with the stamens in the gynosteme. The pollen contained in the anthers is sometimes pulverulent and free, but more frequently waxy or granular, with the grains cohering in masses, which are called scitile masses; these have often prolongations, called *caudicula*, by which they are attached to a viscid gland that has been named *retinaculum*.

The fruit in the *Orchidæ* is capsular; seeds small and many; their reversed gynandrous flowers and coherent pollen distinguish them from other sections. The *Orchidæ* have the flowers monandrous and the germen one-celled. The *Cypripediæ* have diandrous flowers, and germen one-celled; and in the section *Apostasiaceæ*, the flowers are diandrous or triandrous, the anthers discrete, and the germen trilocular.

The *Orchidæ* are more prized for their beauty and the strangeness of their flowers than for any very important dietetic or medicinal properties they possess. The tubers, however, of some of them contain farinaceous matter which is nutritious. The substance known by the name of *salep* is made of the tubers of some of the English species of orchis. It used to be sold at the corners of the streets in London, and was a favourite drink of hard-working people; and it is highly esteemed both in Turkey and Persia, under the name of *sahleb*.

Vanilla is the produce of the *V. aromatica*, the old *Epidendrum vanilla*. This plant is a climbing epiphyte, growing in both Indies, and its root is used for flavouring chocolate, and also for perfuming snuff.

So many of the *Orchidæ* are now in our collections that houses are specially erected for their preservation and culture, almost all the tropical species requiring a strong moist heat. Some of their flowers are most splendid, and all are remarkably curious and some are delightfully fragrant.

The habitat of many *Orchidæ* is on the trunks and branches of trees, though they are not parasites, their food being chiefly extracted from moist air. Hence their culture is difficult, as the roots require very peculiar media to expand in, and these are particularly liable to be preyed on by woodlice.

ORIOLE (*Oriolus*). A genus of omnivorous birds which, in the older systems, included a great many species both of the eastern continent and of America. Further discoveries have led more modern ornithologists to separate them, and form the American ones into a group consisting of two genera, of which some notice will be given in the article TROUPIALES. In consequence of this, the genus *Oriole* is now restricted to birds of the eastern continent, to all of which the same generic characters apply much better than they do to the western ones. There is one external appearance which is rather striking in these birds, and that is the tendency to have their plumage of a brilliant golden yellow, which is of course the reason of their having been originally termed orioles, the meaning of which is nearly synonymous with golden birds.

The characters of the genus are: the bill in the form of a lengthened cone, compressed horizontally at its base; the upper mandible strengthened by a keel along the ridge, notched toward the tip, and both mandibles with strong tomlia or cutting edges; the nostrils are lateral, naked, and pierced in a large

membrane; the feet have three toes to the front and one to the rear, the outer one joined to the middle one at its base; the wings are of moderate length, with the first quill shorter than the second, and the third the longest in the wing.

In some respects the orioles bear a resemblance to the thrushes; but still the differences between them are such that they cannot be brought into one genus. They are more decidedly woodland birds than the thrushes are, and they perch and also build their nests in more elevated places. They also belong to more southerly climates than the thrushes, and are more migratory than the typical species of these. They generally live in pairs, and construct their nests with great neatness, working an external basket of vegetable fibres, which they afterwards line with softer and warmer matters, such as down, feathers, and the substance of spider's webs, the last of which are often found in great abundance, and of no inconsiderable strength, in the places which these birds inhabit.

Their feeding is indiscriminately animal and vegetable; but, when they have recourse to the latter, they prefer such substances as are soft and succulent, such as different sorts of berries. Their animal food consists indiscriminately of insects, small mollusca, and worms. They are all tolerably well characterised both by their expression and by the colours of their plumage. Yellow and black are the prevailing colours of the males; and greenish-yellow and blackish those of the females. The young males resemble the females, and do not acquire the characteristic dress of their own sex until the third year. We shall very shortly notice the leading species.

O. galbula—the European Oriole—is one of the most showy of European birds, though it is rather confined in its distribution, and does not make its appearance in Britain, except as a very rare straggler. On some parts of the continent it is plentiful, however; and it is especially so in Germany, which is, generally speaking, a well-wooded country, and which opens up a passage for birds of an eastern migration, as well as for those which migrate in the direction of the meridian. Those eastern birds are not so ready to come to Britain as the birds of the south, even though they should naturally belong to more temperate climates. Eastern birds find their way across the narrow seas between Europe and Asia Minor; whereas birds that come from the southward of the Mediterranean must take the breadth of that sea in some longitude or other, and there are but few islands on the way to serve them as resting places. Hence we find that the southern bird, after passing over one sea, hesitates much less in taking its flight over another, than a bird which has made the greater part of its journey over land.

The colours on the male bird of the European oriole are fine yellow and pure black. The first occupies both the upper and under parts of the body, with the exception of a little spot of black on each side of the upper mandible above the eye. The prevailing colour of the wings and tail is black, with a yellow spot on the middle of the wing, slight margins of whitish yellow to the tips of the quills, and the tail black with a whitish-yellow border to the feathers, with the exception of the two middle ones. The bill of the male bird is red. The female is olive green on the upper part, and grey mottled with yellow and small black lines on the under part. These birds are

so plentiful in Germany and some parts of France, that they are sometimes styled German thrushes. In France and various other parts of the European continent the golden oriole resides during the summer, and breeds there. About the end of May it is seen in the neighbourhood of Paris, and it generally takes its departure about the beginning of September. When they first arrive, they are so fatigued and emaciated that the sportsman finds them an easy prey, for, when they are feeding, he can approach within gunshot of them before they attempt to rise. Soon after their arrival, however, they commence pairing. They pass Malta in September on their way to more southerly climates, and return by the same route to their northerly habitations in the spring. Retzius informs us that they visit Swedish-Finland about the latter end of May, and leave that locality towards the middle of September. There are not many well-authenticated instances of their appearance. Insects, worms, and caterpillars constitute a considerable portion of their food, but they have also a great partiality to cherries, berries, and other sweet fruits. Their nest has the appearance of a shallow basket. It is suspended by the edge from the forked end of some slender twig or branch. It is a remarkably neat and highly-finished structure. The forked ends of two branches are wreathed together with vegetable fibres, the two extremities of the branch being connected for the purpose of forming the base of the nest. The straws are then neatly adjusted and curiously interwoven from one side to the other, and forming a cavity in the centre. As the work proceeds, the structure is thickened with the finer grasses intermixed with mosses and lichens; and, to complete the work, it is finely lined with the most delicate substances that can be procured, such as the silken bags of the chrysalides of moths, spider's webs, and other soft materials. So soon as this luxurious habitation is completed, the female deposits her eggs, which are generally four or five in number. They are of a dirty white colour, mottled with blackish-brown spots, which are thickest at the larger end. The sitting lasts twenty-one days. The parents are very bold and courageous in defence of their young, which they feed on caterpillars, bringing generally not fewer than ten or a dozen of these to the nest at a time. Such is the parental affection of the female for her progeny, that she has been known to suffer herself to be captured rather than abandon her post while in the act of incubation. This bird has a loud shrill and somewhat disagreeable note, which is preceded by a kind of mewing sound. In captivity it rarely lives above two years, and it is not tamed without a good deal of difficulty. When in this state, it is subject to a goutish affection in the feet, which generally terminates its existence. When fed with a plentiful supply of figs, grapes, berries, and other sweet fruits, it is reckoned a great delicacy as human food. As we noticed, these birds are very lean and exhausted on their arrival from the south, which appears to establish the fact that they do not quit their southern abodes until they are actually driven by famine. On their return southward, however, they are in far better condition, and the people of Italy and, also, of Egypt, eagerly seek after them for the table. According to the ordinary British notions of dainty fare, they would not be highly prized; because they belong to the omnivorous section of birds, the flesh of most of which is unpleasant both to the sight and to the taste.

The remaining species resemble this one so much that it will not be necessary to give more than a brief catalogue of them.

O. chinensis is a species of eastern Asia, where its summer range extends from the southern part of the Oriental Archipelago northward into China. In many respects it resembles the European one; but it is a larger bird, and there are some differences in the colours of the plumage. The coverts of the wings are yellow, and there is a conspicuous black band passing the base of the bill, and extending over the eyes to the occiput.

O. paradiseus is another species of the south-east of Asia, found in those islands which may be regarded as the head-quarters of the birds of Paradise; and for this reason it was formerly classed with them under the name of the orange bird of Paradise. The throat, the base of the bill, and a large portion of the wings and tail, are black, with the exception of some small yellow spots near the extremity of the principal feathers. The head, the neck, and the mantle of very long plumes with which the neck is ornamented, are brilliant orange; and the greater part of the rest of the body is yellow. The male, with the produced feathers on the neck, is a very splendid bird, but the female and the immature males are without the produced feathers, and dressed in sober olive.

O. regens—the Prince Regent Oriole, is a finely coloured species, and native of New Holland. The prevailing colour is an intensely rich velvet black, with the upper part of the head and neck covered with very closely-set feathers of brilliant orange, and the secondary quills of the wings are bright yellow.

O. variegatus is another New Holland species, more diversified in its plumage than these birds generally are. The front of the head is black, and the rest of the upper part is mottled with black, green, and white; the under part of the body is white, with black spots; the tail is blackish, with a bluish-grey margin, and a large white spot on the lateral feathers.

O. viridis is another Australian species. It is generally of a pale green colour, with the lower part whitish, mottled with brown and black spots on the throat; the wings and tail blackish; the bill horn colour; and the feet black.

O. xanthonotus. This is a much smaller species than any of the rest, and has been observed in Java. It is only between six and seven inches in the total length. The male has the back and scapulars of a bright yellow colour, and the under side of the tail and the inner webs of its lateral feathers the same. The other parts are black, with the exception of the belly, which is white, excepting a few minute black spots.

Such are the principal species of the orioles. Two or three African ones have been mentioned, but they do not appear to differ materially from the one which migrates between Europe and Africa. Orioles are not only very handsome birds, but they are highly useful in those countries which they visit in numbers. They eat a good deal themselves, and they collect diligently for their young, so that they destroy a vast number of the caterpillars of those insects which are most destructive to trees. They all belong to tropical countries, or at least resort seasonally there; and though they consume a good deal of small fruits on their return to the south, they more than repay the injury by their labours in the early part of the season.

ORNITHOGLOSSUM (Salisbury). A small

genus of bulbous plants, from the Cape of Good Hope. They belong to the sixth class of sexual botany, and to the natural order *Melanthaceæ*. They are treated like other Cape bulbs.

ORNITHOLOGY. That department of natural science which treats of birds. On many accounts it is the most interesting portion of the science of animated nature. Birds are the most elegant of animals; they have the most numerous and varied motions, and they have more command of the earth than any other class, in consequence of being able to range from country to country with great rapidity, and comparatively little fatigue. They are therefore better indexes to the seasons, and to the state of nature in countries remote from each other than any other animals. A pretty full account of their structure and principal actions and habits, together with the structural arrangement of them will be found in the article BIRD in this work.

ORNITHOPUS (Linnæus). A genus of European annuals, belonging to *Leguminosæ*. One of them, the *O. sativus*, is cultivated in Portugal. It is the bird's-foot of English botany.

ORNITHORHYNCHUS. A most singular genus of Australian mammalia, of which neither the physiology, nor the proper place in the systematic arrangement of animals, can yet be said to be determined in a satisfactory manner. That it belongs to the mammalia, and not to any other class, is established by the fact of milk glands, and milk itself being found in the female, though differing both in their structure and their external appearance from those of every other animal which is known to give suck.

The habits of the animal are, however, so obscure, it is so timid, and has been so nearly extirpated from all those places of Australia which are near the chief settlements, that no opportunity has hitherto been afforded of ascertaining in what state the young are produced. That there is a greater advance in substance, or accumulation of matter, in the young of these animals, before there is any specific development of structure, than there is in the young of typical mammalia which are placental, is unquestionably true. This fact, which, as we shall see afterwards, might have been inferred from analogy, was ascertained from actual observation by the Hon. Lieut. Maule, whose leisure and opportunities gave him every facility for acquiring a knowledge of the animal; and the short passage which contains the statement of this fact, contains also so many traits of the habits of the creature, that we shall give it in his own words. "The *Platypus*," (another name for the *Ornithorhynchus*.) says he, "burrows in the banks of rivers, choosing generally a spot where the water is deep and sluggish, and the bank precipitous and covered with reeds, or overhung with trees. Considerably below the stream's surface is the main entrance to a narrow passage, which leads directly into the bank, bearing away from the river (at a right angle to it), and gradually rising above its highest water-mark. At the distance of some few yards from the river's edge this passage branches into two others, which, describing each a circular course to the right and left, unite again in the nest itself, which is a roomy excavation, lined with leaves and moss, and situated seldom more than twelve yards from the water, or less than two feet beneath the surface of the earth. Several of their nests were, with considerable labour and difficulty, discovered. No eggs were found in a perfect

state, but pieces of a substance resembling egg-shell were picked out of the debris of the nest. In the insides of several female *Platypti* which were shot, eggs were found of the size of a large musket-ball, and downwards, imperfectly formed, however, namely, without the hard outer shell, which prevented their preservation."

That the ova of so small an animal as the ornithorhynchus should equal the size of a large musket-ball, before there is any appearance even of rudimental organisation in them, is certainly different from what occurs in placental mammalia of the same or even greater size. But whatever may have been the size, it is perfectly clear that they were not eggs in the ordinary sense of the word, in which an egg means a germ which, when matured, and still without even the slightest development of organs, is entirely separated from the parent animal, and developed by the heat of that animal or of another, by artificial heat, or simply by the natural heat of the ground, as it may happen. The egg so produced contains in itself all the essential elements of the animal, and wants neither a supply of substance or of food from the mother.

There are two stages in the process even here. The germ, like the germs of all animals, has its essential part formed in the ovary of the female; and though it descends into another vessel, in order to be perfected, the chief additions which it receives there are merely an increase of size, and the hard external shell, by the maturing of which it appears to be finally severed from its connexion with the mother. But the largest germ which Lieut. Maule found in the female ornithorhynchus, had no shell, or firm external covering, by means of which it would be preserved; neither does it appear that it indicated the slightest tendency to the formation of one. Regular oviparous animals, or those which deposit their eggs, so that they are hatched externally, always produce them, if mature, with a firm covering. In some, as in the shells of birds, this covering contains a good deal of salts of lime; whereas in other animals it is more gelatinous, and in some it is flexible. In all, however, it is of sufficient strength to protect its contents from those casualties to which their external situation would expose them; and there are many instances in which, though the life of the animal producing the egg is very easily destroyed, the egg itself is durable beyond any known animal in the organic state.

In the second case, or in that of ovoviviparous animals of which the only known vertebrated ones are either reptiles or fishes, there is always an integument to the egg, which cuts it off from all communication in substance with the body of the parent, as soon as it comes to maturity. After this it merely receives, within the body of its parent, that particular kind of protection and stimulus which are necessary for its development. Thus, though the situation and the circumstances in which it is placed during the hatching, differ in the oviparous and the ovoviviparous animal, it appears that in the state of the egg itself, as indicating a certain stage in the progress from the rudimental germ to the fully developed animal, there is scarcely any difference.

Both from this analogy, and from the physiology of the marsupial mammalia, it does therefore really appear, that wherever the young of the ornithorhynchus may receive its organic structure, it cannot with propriety be called ovoviviparous, in the proper sense of

the word, any more than it can be called oviparous, as it has been done by those who fancied they got possession of its eggs. The germs which have been actually found in the female, whether of larger or smaller size, have never been in a state for final separation from the body of the mother, or even in the slightest progress for being so separated, until some organic development had taken place.

To have a right understanding of the physiology of this most singular of all mammalia, we must therefore, in the absence of certain information, which, from the obscurity of the subject, is probably unattainable, seek for our analogies in another quarter. Now we find that in the kangaroos, and other typical marsupial animals, which there have been opportunities of observing, the placental separation, if placenta there be, in cases where no organ is distinctly evolved by placental action, takes place before the animal produced is capable of performing any one animal function. But then, when discharged from its internal lodgment, the rudimental animal is not in such cases, hatched like an egg, by the application of external stimuli operating upon it through an integument, which forbids the reception of any new matter. The nipple is developed for its reception; and a new attachment, and direct communication of substance by the parent to the young is established, and goes on until it gradually passes into a supply of milk to an animal tolerably perfect in its organisation, as is the case in the common mammalia. In those marsupial animals which have this type in their skeletons, but which have the marsupium so little developed in ordinary cases as to be incapable of receiving the young, we know very little of the young when first produced, for we are not aware of a single instance in they have been found until so far developed as to be able to cling to the mother and perform the operation of sucking. The absence of information with regard both to the mother and the offspring, in this stage of the process, is evidence that the conduct at this time is obscure and concealed. The analogy also points out, that it is to such animals that the ornithorhynchus ought to point, in this particular stage of its being. We know that placental mammalia come into the world in very different states of development; some so far advanced as to be able, in a very short time, to move about, and partially to find their own food. Others again are so backward in their development, that if left to themselves they would inevitably perish.

If we find this difference among placental mammalia, none of which can be said to have anything of a gestation external of the uterus, we may surely be prepared to expect it in marsupial animals, the process of whose development passes through a stage more than the others. The state of the young ornithorhynchi, as found in the nest, tends to show that when there they make a close approximation to the young of the other marsupialia in the early stages of their organic development. A description of the young of this animal, abridged from an able exposition by Richard Owen, Esq., one of our best and most candid physiological anatomists, contains so many particulars, bearing closely upon this most singular and most mysterious point in animal history, that we shall lay them before our readers, as they appear in the proceedings of the Zoological Society of London, a small work, but one in which an immense volume of first-rate talent is concentrated. "The circum-

stances which first attract attention in these singular objects are the total absence of hair, the soft and flexible condition of the mandibles, and the shortness of these parts in proportion to their breadth, as compared with the adult. The tongue, which in the adult is lodged far back in the mouth, advances in the young animal close to the end of the lower mandible, and its breadth is only one line less in an individual four inches in length than it is in fully grown animals; a disproportionate development, which is plainly indicative of the importance of the organ to the young ornithorhynchus, both in receiving and swallowing its food. On the middle line of the upper mandible, and a little anterior to the nostrils, there is a minute fleshy eminence lodged in a slight depression. In the smaller specimen this is surrounded by a discontinuous margin of the epidermis, with which substance, therefore, and, probably, from its having been shed of a thickened and horny consistency, the caruncle has been covered. It is a structure of which the upper mandible of the adult presents no trace, and Mr. Owen regards it as analogous to the foetal peculiarity of the horny knob on the upper mandible of the *bird*. He does not, however, conceive that this remarkable example of the affinity of the ornithorhynchus to the feathered class is necessarily indicative of its having been applied, under the same circumstances, to overcome a resistance of precisely the same character as that for which it is designed in the young bird, since all the known history of the ovum ornithorhynchus points strongly to its ovoviviparous development. The structure of the eyes is indicated by the convergence of a few wrinkles to one point; but the integument is continuous, and completely surrounds the eyeball. In the absence of vision in the young animal, strong evidence is afforded of its being confined to the nest, there to receive its nourishment from its dam; and this deduction is corroborated by the cartilaginous condition of the bones of the extremities, and by the general form of the body: the head and tail are closely approximated on the ventral aspect, requiring strength to pull the body into a straight line; and the relative quantity of integument on the back and belly shows that the position necessary for progressive motion is natural at this stage of growth. Mr. Owen describes other external appearances of the young ornithorhynchus, and then enters at considerable length into its anatomy. The stomach is nearly as large in an individual four inches in length as in the adult animal. In this specimen it was found filled with coagulated milk, and no trace was visible, on the most careful examination, of worm or bread, on which, up to the time of his discovery of the mammary secretion, lieutenant the honourable Lauderdale Maule had believed that this individual had been sustained. A portion of this coagulated substance was diluted with water, and examined under a high magnifying power in comparison with a portion of cow's milk coagulated by spirit, and similarly diluted. The ultimate globules of the ornithorhynchus's milk were most distinctly perceptible, detaching themselves from the small coherent masses to form new groups: the corresponding globules of the cow's milk were of larger size. Minute transparent globules of oil were intermixed with the milk globules of the ornithorhynchus. A drop of water being added to a little mucus, it instantly became opaque, and its minutest divisions, under the microscope, were into transparent angular

flakes, entirely different from the regularly formed granules of the milk of the ornithorhynchus."

There are many highly interesting points in these remarks of Mr. Owen, which would bear, and indeed which require, more making out, and less disposition to be fettered by the insinuating doctrine of affinities, that appears even in his account. The hardened knob on the upper mandible, for instance, cannot be regarded as having the slightest resemblance to the enlargement in the tip of a young bird's bill, and that for this obvious reason; the appendages to the jaws of the young ornithorhynchus, are not mandibles, but really lips adapted for sucking, and the tongue is a sucking tongue. The knob upon the upper lip is clearly intended for assisting the young one in obtaining milk from the mammary apparatus, which, from the large size of the stomach, it evidently does in very considerable quantity. This agrees with the very partial development of the young as at first seen, and the maturity at which they arrive before leaving the mother, and also the comparatively rapid rate at which this development takes place. In many of the regular mammalia, and even in the human subject, the inside of the upper lip is provided with a knob much firmer than the rest of its substance; and there seems little doubt that this knob operates in some way in pressing the mammary apparatus. There is no regularly formed teat upon that apparatus in the female ornithorhynchus; and thus there is little doubt that the knob upon the upper lip assists in pressing the mammary glands so as to obtain the requisite supply.

The quotations and remarks which have been made, embody the greater part of the knowledge which we at present possess respecting the physiology of this very singular animal, and, taking the general scope of them, they completely refute the notion of its being oviparous, and render that of its being ovoviviparous exceedingly doubtful; but till the facts between what has been last observed of the internal germ, and what first of the produced young, have been ascertained so as to complete the series, some doubt must remain; and doubt of such a nature, as not to be removed without the greatest difficulty. The chief difficulty appears to consist in this, that the female, at the time of parturition, never makes her appearance; and the nest is so concealed in its entrance, that it is scarcely possible to detect her there, except by one of those accidents which can be but rarely looked for in those wild and unfrequented parts of a savage country which the animal inhabits. All the authorities agree, that the burrows of these animals are formed in secret, and the entrances of them are carefully concealed. The water line is the elevation at which the burrows of aquatic mammalia generally open: but these have two openings, one below the surface of the water, and the other at a considerable elevation above it, but always so hidden among the herbage, that it is impossible to know where to look for them. They are dug to a great length, sometimes as much as fifty feet, and seldom less than thirty. They are winding in their direction, and incline upwards; but the animal never throws up any heaps on the surface, or leaves any excavated earth at the entrance. It is probable, therefore, that it bores into the earth by the forward pressure of its body, as the mole sometimes does, and does not remove any of the earth with its claws. The fore paws, which are the effective digging instru-

ments in all burrowing mammalia, are not, indeed, very well adapted for scraping the earth, though the claws upon the toes are strong. The web, though it can be retracted, would be much in the way in such an operation, though it might assist the animal in pushing itself forward, and also in patting and smoothing the burrow after being once formed. The working of the animal in the formation of its retreat is as obscure, however, as the undetermined part of the mode of its production.

Mr. Bennett, who was at great pains in finding out all the observable habits of these curious animals, mentions, that the utmost caution is necessary in getting a sight of them when they come to the surface of the water, as the least sound or even motion in an observer, when sufficiently near for getting a view of them, is sure to send them under water, and they do not rise again at the same place. One who remains perfectly still and quiet, may observe them paddling about for a minute or two. They soon descend, however, even when not alarmed; and if the least alarm is given, they descend instantly, plunging head foremost. A sketch of one in the act of swimming at the surface, was given in the article MAMMALIA, at page 197 of this volume; and there is also a figure on the steel plate, entitled "AMPHIBIOUS ANIMALS."

In the interior chamber of the burrow, the female constructs rather a comfortable bed for the young, consisting of dried vegetable matters; but as most burrowing animals construct beds of this kind for their young, no particular conclusion can be drawn from this circumstance.

Their food is understood to be obtained entirely in the water, or rather in the soft mud and sludge at the bottom or close by the margins. It is understood to consist entirely of animal matter—insects and their larvæ and small mollusca. They feed after the manner of the dabbling ducks; though, as their feeding is generally under water, it is not easily observed.

Long as Australia has been a British colony, and many of these animals as have been captured, it is somewhat remarkable, that it was not till Mr. Bennett made his observations in that country, that any thing was known of their dispositions. The spurs on the hind legs had long been regarded as inflicting poisoned wounds; but Mr. Bennett teased and irritated the male, the only one which has these spurs, in a variety of ways, and the animal never showed the least disposition to use the spurs, or any other part of the body, either for offence or defence. The probability therefore is, that in all respects these are among the most harmless of animals. They are not, however, destitute of kindly and playful dispositions, or even of resources for the accomplishment of purposes very unsuitable, as one would suppose, to their very singular organisation.

In the course of his researches, Mr. Bennett succeeded in procuring from the nest two young ones, sufficiently advanced to have the fur complete; and he contrived to keep them not only alive, but in health and playfulness for some time, though, probably from the want of food rightly adapted to them, they soon languished, and died at the end of five weeks, thus defeating Mr. B.'s hope of bringing them alive to England. While they were in his possession, he was watchful of their manners; and the results of his observations are valuable, as containing all that is known on the subject.

They were obviously much attached to each other, and slept great part of their time. When sleeping profoundly, they could be handled without complaining; but when their sleep was less perfect, they uttered "awful little growls," as Mr. Bennett expresses it. Sometimes they slept with their bodies extended; and at other times they rolled themselves into balls. In doing this the head is bent backwards, and the tail forwards on the under part, so that the tail extends over the head, as is done by most animals which roll themselves up without having a contractile case like that of the hedgehog. They used to play with each other, using both the mandibles and the fore paws in their little sham fights, and continuing till one was upset. There never appeared, however, to be the slightest tendency to triumph on the one side, or to irritation on the other in these displays; for when one was down the other always waited till it got up again; and the fallen one very frequently took the opportunity of trimming its fur with the hind feet; and both of them would sometimes pause and perform this operation, which appears to be a very common one with the animals when they come on land.

One of the most singular indoor exploits was that of climbing to the top of a book-case; and their mode of doing this shows something of their manner of proceeding when they work their way in the earth. The book-case stood within a short distance of the wall; and the animal by getting its paws to the book-case, and its back to the wall, and working the muscles of both, contrived to make its way to the top with more celerity than one would have expected from its apparent slowness and helplessness on the surface of the ground. The form of the body, and the nature of the fur appeared both to assist in this kind of motion. The back is exceedingly muscular, and the legs very short, while the smoothness of the fur favours a forward motion, and its stiffness prevents a backward one; and by thus working double, it is probable that these animals can move with great rapidity and little labour along their subterranean retreats. For some account of the swiftness of another burrowing animal under ground, as compared with its helplessness upon the surface, see the article MOLE in the present volume. This climbing seemed to be a favourite style of motion with these curious animals; for they obtained no food or any other gratification of a desire, as the reward for it, and yet they practised it again and again, appearing to take a great pleasure in it.

Mr. Bennett paid attention also to their aquatic habits, in order that he might establish something with regard to their manners in both elements. He took them to the water, using the precaution of securing them by a cord fastened to the hind leg, in order to prevent their escape. They entered it readily, swimming about and feeding, and resorting in preference to places containing aquatic plants for the latter purpose. When they had wearied themselves in this way, they returned to the bank, trimmed their fur with their claws, and fell into a state of repose; and there is little doubt that such is their habit in a state of nature, only they retire to the burrow instead of reposing on the bank.

Such is the most authentic account which has hitherto been received of the disposition and manners of these curious animals. We may add, that the length varies from fifteen inches to upwards of two

feet, the dimensions of the female being inferior to those of the male. The long silky fur on the body is dark brown, the downy fur grey, and most abundant on the under part of the animal. The tail is flattened, has an up-and-down motion in swimming, and is about one fourth of the length of the other parts.

ORNUS (Persoon). A genus of deciduous trees, natives of Italy and North America, and commonly known by the name of the flowering-ash. The flowers are diandrous, and the genus ranks among the *Oleaceæ*. These grow with us to be middle-sized trees, and their tufts of flowers are rather showy. They may be raised from seeds, but they are most commonly increased by grafting upon the common ash.

OROBANCHEÆ. A small natural order, containing only two genera, viz., *Lathræa* and *Orobanche*, of which there are seven species, six of the last and one only of the former. They are mostly parasites, living either upon dead or living plants. The *Lathræa* is found on the roots of trees in shady woods, and provincially called tooth-wort, from the scales on the stem resembling teeth. The *Orobanche*, *minor* and *major*, are found growing on the roots of common broom (*Genista tinctoria*), hence called broom-rape, but much more frequently on the roots of the red or broad clover, and in such quantity as to form one-third of the second crop, being, however, a very useless addition, as it is a robber of the clover as well as the broom. The *O. ramosa* is a parasite on hemp. They are leafless plants, having scales occupying their place.

OROBUS (Tournefort). A genus of perennial herbs, mostly European. They bear pretty diadelphous flowers followed by pods, which places them in the order *Leguminosæ*. They are called the bitter-vetch, and several of them are cultivated as ornamental plants.

ORPIMENT. This valuable mineral is much employed as a pigment. It was formerly better known as ruby sulphur. The primitive figure of the red orpiment is an oblique four-sided prism, and two of its most common secondary figures are represented in the annexed engraving.

It occurs most frequently in veins in gneiss and clay-slate, and it is usually accompanied with arsenic. Yellow orpiment is of a lemon colour, and is rarely found in the same situations as the preceding. It is found in great beauty at Andreasburg in the Hartz mountains.

ORPINE is the English name of the *Sedum telephium* of Linnæus, a British plant found in hedge banks. The genus *Telephium*, a south of Europe plant, is also called *Orpine*.

ORTHOCERAS (Dr. R. Brown). A New Holland genus, belonging to *Orchideæ*, introduced about 1826. It is a cold frame plant.

ORTHOPOGON (Dr. R. Brown). A genus of tropical *Gramineæ*, one of which, the *O. hirtellus*, is cultivated in the West Indies.

ORTHOPTERA (Olivier). An order of mandibulated insects, united by Linnæus at first with the coleoptera, and afterwards arranged by him with the haustellate hemiptera, from the construction of the wings. By Geoffroy they were also arranged with the coleoptera, forming the third primary division of that order.

De Geer, however, saw the impropriety of retaining these insects in either of these two classes, from each of which they differed in the structure of the wings and mouth, or in the nature of their metamorphoses, and accordingly raised them to the rank of a distinct order, to which Olivier subsequently gave the name of *Orthoptera*, from the longitudinal or straight (*ὀρθος*) folding of the wings (*πτερά*). Fabricius had also raised these insects to the rank of an order which he termed *Ulonata*, from the Greek *ουλος*, an outer gum, and *γυαθος*, a jaw, the lower jaws being laterally armed with a helmet-like plate, which is in fact but the greatly developed external lobe of the maxillæ. See vol. ii. p. 853, fig. 104, c.

The body in these insects is generally of a large size, less firm in its consistence than in the coleoptera, with the tegmina or wing-covers soft, coriaceous, provided with numerous nervures, and not uniting when closed in a straight line down the back; the wings are membranaceous, and furnished with equally numerous nerves, arranged longitudinally, with transverse threads, so that the wings fold up something like a fan; the mouth is furnished with a very considerably-developed organ, which is the analogue of the tongue. These characters alone would suffice to point out their differences from the coleoptera, in which the outer lobe of the maxillæ is not helmet-like, and the wings are transversely folded, whilst the mouth in the hemiptera is not formed for mastication, being unprovided with jaws, and the wings are simple, extended, when at rest, beneath the wing-covers, without being folded.

The head of orthopterous insects is in general large, and almost perpendicular in the majority, the antennæ being placed on its upper part, and which are of variable length and structure, but often long and multiarticulate; the eyes are large and lateral; and the ocelli which are found in the majority are placed on the forehead, sometimes widely apart; the thorax, or, more strictly speaking, the pronotum, is large, being in many species extended considerably backwards; the abdomen is long, generally of a conical form, and terminated in the females of many species by an exerted apparatus for depositing the eggs in the shape of a sword or cutlass.

The legs of the *Orthoptera* are very long, and are employed in giving considerable activity to these insects, in some of which these organs are simply organs fit for walking (*Blatta*); in others the fore pair of legs become instruments for seizing their prey (*Mantis*); whilst in the rest the hind legs are greatly increased in size, supporting strong internal muscles, enabling the insect to effect leaps of great extent; these legs are also employed in some species to produce a loud chirping noise by their friction against the base of the wing-covers (*Locusta*), which noise appears to be the call of the males, by which sex alone it is produced. We have already, in the article GRASSHOPPER, given a more detailed account

ORTHOPTEROUS INSECTS.

Prisopus hortatus W.
(*Alutaceus*)

Metalliticus splendens W.
(*Malabar*)

Tripetalocera ferruginea W.
(*Malabar*)

Scaphura kirilii W.
(*Dread*)

Schizodactylus monstrosus.
(*India*)

of the modes by which this chirping noise is produced, and which it will therefore be unnecessary to repeat in the present article. The tarsi vary, in the number of the joints, from three to five; generally speaking, the body is long, and often much compressed.

The nature of the metamorphoses of these insects is also another great character by which they are distinguished from the coleoptera, the larvæ and pupæ differing only from the imago, either by entirely wanting, or having only rudiments of wings. The larva and pupa of the great green grasshopper are represented in vol. ii, page 839, figs. 30 and 31. In these states the insect is as active and as voracious as in that of the imago.

If we had cause, in treating of the hymenoptera, to admire the admirable displays of instinct which they afforded us, we are here compelled to admit that the present order cannot bear anything like a comparison in the means of attracting our attention. They, however, amply perform their work in the great labours of the economy of nature, for they are amongst the most voracious of the insect tribes. The cockroach, the mantis, and the locust, are too well known in this respect to require more than the insertion of their names to bring before us the great and occasionally overwhelming ravages which they commit. Their food, for the most part, consists of vegetable substances, and which, being less serviceable for the purposes of animalisation than animal matters, it is necessary that a much greater quantity of food should be taken, in proportion to the size of the insects, than is consumed by the predaceous species which feed on other insects, or upon carrion. Hence, from their great size, the *Orthoptera* may be regarded as the most pre-eminently herbivorous of the insect tribes, and their voracity is excessive. We need only refer to our article LOCUST for a confirmation of this statement, whilst the article COCK-ROACH furnishes sufficient proof of the in-door devastation which the insects of this order are capable of performing. The internal anatomy of this order is organised in a manner adapted to their herbivorous qualities. The alimentary canal is greatly elongated, and divided into several chambers or stomachs; four of these have been attributed to the mole-cricket, whose internal structure has been long ago investigated, and more recently by Dr. Kidd, of Oxford. From this circumstance it has been supposed that the *Orthoptera*, analogous to the ruminating quadrupeds, had the power of bringing back into the mouth aliments which had already passed into the stomach. According to M. Marcel de Serres, these chambers are not in fact stomachs, but merely contain a salivary and biliary fluid, which the animal often disgorges when seized. The internal structure of the larva does not differ from that of the imago.

All the known species of this order are terrestrial. Stoll has indeed represented an extraordinary insect, belonging to the order, as an aquatic species, but there is no confirmation of this circumstance.

The species found in our part of the world deposit their eggs but once in the year, which takes place at the end of the summer, when they have assumed the perfect winged state. They perish at the approach of winter, and the species are perpetuated by the eggs remaining unhatched, during the winter, in the earth where they were deposited, the larvæ coming forth in the following spring.

It is difficult to preserve the insects of this order, without considerable attention, in our collections, the body, being moist and fatty, attracting destructive insects, such as the *Anthrenus*, *Dermestes*, &c. It is on this account that some of the species, which are natives of Africa, are eaten by the negroes, who have thence obtained the name of *Acridophagi*.

The order, excluding the earwigs (order *Dermaptera*, Leach, see *EARWIG*), and including the cockroaches (which Dr. Leach separated as an order under the name of *Dictyoptera*), is divisible as follows:—

Section A. CURSORIA.—Hind legs formed for running or walking; wings and wing-covers generally horizontal; females not provided with a horny exerted ovipositor.

Fam. 1. *Blattidæ*.—Tarsi five-jointed; head hidden beneath the shield of the thorax; body flattened and oval, or rounded. (Cock-roaches).

2. *Mantidæ*.—Tarsi five-jointed; head exposed; body long, and generally narrow; fore legs raptorial. (Preying mantis.)

3. *Phasmidæ*.—Tarsi five-jointed; head exposed; body long, and generally narrow; fore legs not raptorial. (Spectre insects.)

Section B. SALTATORIA.—Hind legs formed for leaping; wings and wing-covers generally deflexed at the sides; females generally provided with an exerted horny ovipositor.

4. *Achetidæ*.—Antennæ very long; wings and wing-covers horizontal; tarsi three-jointed. (Crickets).

5. *Gryllidæ*.—Antennæ very long; wings and wing-covers deflexed; tarsi four-jointed; ovipositor long, sword-shaped. (Grasshoppers, with long antennæ.)

6. *Locustidæ*.—Antennæ short; wings and wing-covers deflexed; ovipositor short. (Locusts and grasshoppers, with short antennæ.)

The species which we have selected to illustrate this order in our plate of ORTHOPTEROUS INSECTS are, 1st, *Metallicus splendens* (Westwood), from Malabar, a remarkable insect, being the only species of the order exhibiting metallic colours, and belonging to the family *Mantidæ*; 2nd, *Prisopus* (Latreille; *horridus*, Westwood), a singular species of spectre insects (*Phasmidæ*), from Mexico; *Schizodaetylus monstrosus*, from India, belonging to the *Achetidæ*; 4th, *Scaphura Kirbii* (Westwood), from Brazil, belonging to the *Gryllidæ*; and, 5th, *Triptalocera ferruginea* (Westwood), a remarkable insect, from Malabar.

ORYSSUS (Latreille). A very peculiar genus of hymenopterous insects, belonging to the section *Securifera*, and family *Siricidæ*, having the abdomen sessile, the antennæ inserted near the mouth, the maxillary palpi long, and the ovipositor slender, spiral, and internal, in which respect the genus approaches the *Cynipidæ*. There are two European species, which are found upon trees, but they are of very rare occurrence, and of great agility. The description of a North American species is given in the last number of the Zoological Journal.

ORYZA (Linnæus). A genus of useful cereals, belonging to the natural order *Gramineæ*. It is the *Eruz* of the Arabians, and the rice of English authors. In warm climates it is the most valuable necessary of human life, and perhaps it is not beyond the truth to assert, that as great a number of human

beings are supported on rice as on wheat itself. It is the staple corn of the tropics, as the oat is of the northern, and wheat of the temperate regions. The culture, however, is exceedingly unhealthy; for the frequent flooding of the fields keeps them constantly in a swampy state, and favours the production of malaria. Rice has been raised in England on the banks of the Thames, a crop having been gathered in near Windsor. In Italy it is cultivated with success; but artificial irrigation has been carried there to a higher degree of perfection than in any other part of Europe; and without artificial irrigation rice cannot be raised any where. In India and China it is raised on a most extensive scale. Every river is intercepted by a succession of dams to throw out the water, and to form large lakes or tanks for the supply of the rice grounds. Some of these tanks are many miles in circuit; one not far from Madras, says Buchanan, "is eight miles in length, by three in width, and its contents are sufficient to supply with water the lands of thirty-two villages for eighteen months, supposing the usual rains to fall."

Rice is imported into England in large quantities, both from the East Indies and America. Upwards of one hundred thousand bags of rice are now annually imported, and the quantity is gradually increasing.

The Canada rice, although not yet much cultivated, has all the natural capabilities to become a valuable corn. Its grains are large and replete with a fine bland farina. It grows abundantly in the shallow waters of North America, and has been acclimated here; it grows freely in Middlesex and Ross-shire. Attempts are being made, when it is to be hoped will be successful, to cultivate it in Ireland. Pinkerton says, "this plant seems to be designed by nature to become the bread corn of the north."

OSIER. A general name of several sorts of willows, particularly the *Salix rubra* of Hudson, being much used by basket-makers, and for binders in wood-work.

OSMIA (Panzer). A genus of solitary bees, belonging to the family *Apidae*, and subfamily *Dasygastres*, having the maxillary palpi three or four jointed, the abdomen convex above, and of an oval form. Some of the species are mason bees (having habits very similar to those of the *Megachiles*), and their heads are furnished with two or three horns, which are probably serviceable in the construction of their nests, which are hidden in the ground, crevices of walls, old wood, and even occasionally in the deserted shells of garden snails. Of the latter, some particulars are given by M. Robineau Des Voidy, who has obtained two species (*O. bicolor* and a new species which he names *O. heliocicola*) from nests respectively formed in the deserted shells of *Helix nemoralis* and *H. pomatia*. *O. bicolor* lays two eggs in each shell, the female egg being always uppermost; above these are constructed three or four cells of sand separated from each other by a membranous partition. *O. heliocicola* deposits ten or twelve eggs, separated from each other by distinct partitions, each being provided with a magazine of honey; but they do not wall in the different strata either with sand or any earthy matter placed above the domicile of their progeny. They sometimes form their nest in *Helix nemoralis*, in which they lay several eggs, closing the entrance with a thick division formed of minute fragments of leaves

tritulated with the salivated excretion of the insect, and arranged in successive layers. Also, in these two species he discovered a minute parasite, which he named *Eulophus osmiarum*, the larvæ of which, after feeding upon the larvæ of the bees, change into pupæ without spinning a cocoon or quitting the place of their birth.

Other species of the genus clip the petals of flowers, of which they form their cells in the same manner as the *Megachile*; amongst these the *Osmia papaveris*, or the *Abeille tapissiere*, is the most interesting, building its nest with bits of the scarlet petals of the wild poppy; others select for their nest the interior of galls.

OSMITES (Linnæus). A genus of evergreen shrubs, natives of the Cape of Good Hope. They belong to *Compositæ*, are easy of cultivation, and increase in the green-house.

OSTEOSPERMUM (Linnæus). A genus of evergreen shrubs, natives of the Cape of Good Hope, remarkable for the bony hardness of their seeds. They belong to *Compositæ*, and succeed well in the green-house.

OSTRICH (*Struthio*, or rather, perhaps, *Struthionidae*, the ostrich family). The most remarkable of the feathered race, both for the vast size and swift motion upon the ground which some of them possess, and for the fact that the whole of them, without exception, are destitute of flight, and in some the wings are so very rudimental, as not apparently to be capable of any purpose in the economy of the birds. In Cuvier's arrangement, they form the first family of *Echassiers*, or stilt birds, and they differ greatly from all the rest both in their structure and their economy. There are several genera of the family, and each genus has a separate locality, no two of them being found in the same part of the world. They are: the ostrich properly so called, a native of Africa, and of the adjoining parts of Asia; the American ostrich, which is not found except on the dry plains of South America; the *Emu* of Australia, which occurs only in that country, and chiefly, or, at all events, most abundantly in Van Diemen's Island; the *Cassowary*, which occurs only in the south-east of Asia; the *Apteryx*, which is confined to a peculiar district of New Zealand; and the *Dodo*, which, if it ever really existed, had its locality at Madagascar, and probably on some of the other islands to the eastward of Southern Africa. If the last mentioned one ever really existed, it appears now to be extinct, and to have been so ever since the visitors of distant lands paid much attention to subjects of natural history. That birds so singular in their structure should be distributed over parts of the country so widely separated from each other, all different in their generic characters, and each genus consisting only of a single species, is a very curious fact in natural history. It is remarkable too, that those which lie nearest to each other in geographical position, do not resemble each other the most in their structure. The bird of Australia and that of South America have much more resemblance to each other than the bird of Africa, which lies intermediately between them. The New Zealand bird is perfectly unique, not resembling the others in any thing but in being wingless, and it is the most wingless of the whole. Of the bird of the African islands nothing can with certainty be said.

Of the greater number, notices have already been given under their respective names as they are above

OSTRICH.

Female

Male

enumerated; and the reader who wishes for a short account of them may turn to these names in their alphabetical order, with the exception of the ostrich properly so called, and the American ostrich, or *Rhea*, and thus the present article may be restricted to some notice of them.

THE OSTRICH (*Struthio camelus*), is one of the most celebrated birds in the whole annals of the feathered race; and, like all birds and other animals which have been famous from remote antiquity, much that is marvellous has been recorded of it. It is the swiftest footed of known animals; the one which lives most habitually in the desert, and it is remarkable for its proneness to swallow a vast number of substances, and also for the great vigour of its digestive powers, though in the latter respect many tales are reported of it which are totally without foundation—such, for instance, as its power of digesting, that is, of converting into animal nutriment all sorts of stones and metals. Now this is not true; for the greater part of every stone or metal is composed of elements quite unfit for entering into the composition of any animal substance; and it is just as absurd to suppose that the ostrich has the power of converting iron or brass into the substance of its own body, as it would be to suppose it capable of converting its own vegetable food into gold or any other metal.

The generic characters of the ostrich are: the bill of mean length, straight, blunt, and depressed at the point, which is rounded and furnished with a nail. The two mandibles are of equal length; the nostrils are oblong, placed a little on the surface and toward the middle of the bill; the head is naked of feathers and colours on the upper part; the legs are very long and very strong and muscular; each of them has only two toes, the internal one very stout, and furnished with a broad claw; the external about half the length of the internal, and without any claw. The legs are stout and fleshy, nearly as far as the tarsal joints, and they are very free in their motions. There are no wings fit for flight, for both they and the tail consist of long and flexible feathers, quite incapable of acting against the air in any kind of flight. The lower part of the neck, the breast, the belly, and the back are black, mottled with white and grey. The large plumes of the wings and tail are of a white colour, with remarkably flexible shafts, and beautiful loose webs of silky texture, which have from time immemorial been used as ornaments in military and state dresses, and in pageants. The intermediate parts of the skin of the bird are covered with soft down, which appears between the plumes. The bill is grey for the greater part of the length, and black at the tip; and the irides are brownish-yellow. When the ostrich, in its full-grown state, stands with its neck at the full elevation, its total height is about seven or eight feet, and, if in good condition, it sometimes weighs as much as eighty pounds.

It is thus a majestic bird in its appearance, and stately in its gait, from the length of its legs and the stretch, and bounding elasticity of its step. But though it is thus the giant of birds by way of eminence, it is one of the most harmless and inoffensive of the whole race. It offers no voluntary attack upon any animal; and its fleetness is such, that no enemy save man, can master it in those open wastes which form its principal habitation. The eggs of the ostrich are contained in very strong shells, and they are of such dimensions, that a single one weighs about three

pounds. It has often been said that when the female ostrich lays her eggs, she abandons them to their fate, without giving herself any more concern either about them or about her young. Nothing can be more unfounded as a general trait in the character of the ostrich than this. Like all birds which subsist upon vegetable food, which they procure exclusively by walking on the ground, ostriches are social animals, fond of the company of each other; and we are acquainted with no social animal which deserts or neglects its young, and its doing so would be in direct opposition to the social propensity, and thus the character of the animal would be inconsistent with itself, which never happens as a general habit in any one animal whatever.

That the ostrich sometimes does leave her eggs, and that the heat of the sun acting on the dry sand may, in such cases, assist in hatching them, is no doubt true. But even then, the ostrich, if there is only one in the locality, is never beyond the range of her own vision from the eggs; and if an enemy ventures near them, she hastens to the spot, and defends them with great bravery and resolution. When she does leave them in this manner, we may rest assured that there are physical circumstances in the place where they are deposited, which make the process of incubation go on as safely as if the bird herself were present. Though ostriches are confined to the dry and open plains, their range is very wide. They occur from the dry grounds immediately behind the mountains of Atlas in Northern Africa, southward to the country of the Cape. In longitude their range is still greater. It stretches from the western extremity of the African desert, through the dry and naked parts of Arabia, Persia, and the Indian deserts, nearly to the banks of the Ganges. Of course there are many places within those limits quite unadapted for the pasture of ostriches. There are marshes, woods, and cultivated grounds, and the birds are not adapted for either of these, and not found upon them. But within the range mentioned there are ostriches upon every suitable pasture; though Africa, and especially the margins of the great desert in Northern Africa, are the head-quarters where they are found in the greatest numbers, and of the largest size.

Now, in so wide an extent there may be said to be three distinct kinds of locality in which the female ostrich may have to deposit her eggs. In the first place, there are the situations so far into the dry desert, that there scarcely forms any dew during the night; and here the ostrich can afford to be absent from her eggs, during the whole twenty-four hours, if such an absence should be necessary. For the radiation of heat from the sand during the night would be quite sufficient to keep up a stimulus to vitality in the eggs, until the direct sun of another day came upon them. It is in those situations that the ostrich has most occasion to be absent, because the very circumstance of the absence of moisture, which prevents the chilling of the surface by the evaporation of dew, diminishes the quantity of food which the animal can meet with, and this compels her to range over a far greater extent of surface, in order to preserve her own life. Under such circumstances, she also actually requires more food; for the food requisite to the healthy state of an animal, increases with the increase of its labour.

Instead therefore of setting the brand of an unnatural mother upon the ostrich, we find a very

beautiful provision of nature in the mutual adaptation of her and the desert to each other. Not even the smallest bird, or the bird of the swiftest wing could remain and rear a brood in those more arid breeding places of the ostrich; and thus, but for her, a large portion of surface upon which she can subsist, would be a waste in nature; and therefore in opposition to the general laws and provisions of the system.

In the second place, there are situations, less advanced into the dry desert, where, though the day is exceedingly hot and the air dry, dew forms, and the night is cold, especially toward the morning. When her eggs are in such a situation, the ostrich can afford, with perfect safety to them, to range about for her food during the day. It is necessary, however, that she should come and shelter them with her downy feathers during the night, and this she accordingly does. Here again she is enabled to do so from the physical circumstances of the place, because vegetation is much more abundant than in the drier places, and a less range finds her an abundant supply.

In the third place, ostriches are found in localities without the tropics, and so far out of the desert as that the eggs do not derive so much assistance from the heat of the sun; and in these the bird requires to sit more constantly, and she does it accordingly.

Therefore there is not, in the whole range of nature, a more beautiful instance of adaptation than that which subsists between the ostrich and the desert. The desert is a singular locality in nature, and the ostrich is as singularly formed and fitted for the severe labour which it has there to encounter. In its walking structure, the bird is not excelled by any animal, even by those swift antelopes which are her near neighbours. We find too, that wherever one species of action is required in a very high degree, the organisation of the animal is to a great extent concentrated upon that. Flight would have been of comparatively little use to such a bird in the situation in which it has been placed by nature. Wings for flight, to bear up so weighty a bird as an ostrich in swift motion through the air, would have demanded a waste of muscular exertion, for the supply of which sufficient food could not have been found in the ostrich's country. Besides, wings would have been of no use in the desert, because there is nothing there which a vegetable feeding bird could catch upon the wing; and the height of the ostrich, standing on foot, is quite sufficient to reach the top of the tallest vegetable on her pastures. There is therefore a very fine instance of economy in the wings of the ostrich being so little developed as that they are unfit for flight, because this enables the whole power of the bird, in so far as motion is concerned, to be concentrated upon the legs, and the muscles by which these are moved.

A most essential form of the sternum is obtained by this means. A figure of an analogous sternum, that of the Australian emu, may be seen by referring to page 457, of Vol. I. of this work. From that it will be perceived that the keel, essential to the sternum of a bird of powerful flight is dispensed with; and also that the principal articulation is with the ribs, while the sternum is a sort of breast-plate on the fore part of the body; so that the breast can be brought to the ground without any pressure of important parts, in order to enable the bird to fold its very long legs with perfect security, when it is about to repose on the ground. We have no space to go into the particulars, but whoever chooses to do so, possessed of

the proper means of knowledge, will soon perceive that the skeleton of the ostrich is a very fine specimen of animal mechanics.

The system of nutrition in the ostrich is not unworthy of attention. Subsisting upon vegetable matters, which are hard and dry, and from being so requiring a great deal of grinding, the ostrich has a very strong muscular gizzard, firm and compact in its walls. It may be said to have three stomachs, or at all events there is a dilatation between the crop and the gizzard, which must answer some purpose in the economy of the animal. It is no doubt the necessity of some hard substances to act as a second mill-stone in the gizzard in grinding the food, which makes the ostrich so prone to swallow all manner of hard substances, with perfect indifference as to what may be their taste or their smell. The great length of the intestinal canal too, and the size of the cæcal appendage, show that the digestion of this animal is a process of the most laborious kind.

In the matter of sensation, it is probable that the ostrich depends chiefly upon sight. Taste and smell are quite incompatible, either with the finding of the bird's food, or with the swallowing of those substances which assist in the preparation of it. Hearing would also be of comparatively little service in such a bird. The eye is the grand organ upon which the animal depends; and the length of the neck, which corresponds to that of the legs, so that the point of the bill can reach the ground when the axis of the body is in a horizontal position, is well adapted for commanding a very large surface of the desert.

In a state of captivity the ostrich prefers grain to every other kind of food, though it will also eat the leaves of lettuce and other succulent plants. In this state it drinks a considerable quantity; and it is probable that it does so in a state of nature, though the Arabs give a different account of it. There is no doubt that in some of its localities it cannot have very frequent opportunities of drinking, but still there is no ground for believing that it actually abstains from water in cases where it is to be had.

Though not in the least disposed to be pugnacious, and generally inclined to seek its safety in flight, when it has nothing to protect but its own life; yet the ostrich is not unprovided with weapons of defence, which it can use with very considerable force and effect. These weapons are the bill, the feet, and the strong spines of which there are two in each wing. The length of the neck, and the powerful motion which it has, enable the bird to use the bill with great velocity; and we need hardly mention that the velocity of a striking instrument very rapidly compensates for a deficiency of weight or hardness. We find this proved by the fact, that a tallow candle can be shot through a deal board, if it move fast enough, and also from a circular plate of soft iron, not merely cutting the hardest steel, but even setting it on fire, the plate being moved with great velocity, and the steel held against its edge. The feet also derive a very effective power from their length, and the consequent velocity with which the extremities of them can be made to take effect; we have remarkable instances of the powerful kick of a long foot in the giraffe, and the kangaroo, the first of which is said to be capable of stunning the lion, and even of breaking his skull, and the second of serving the wild dog of Australia much in the same manner. Thevenot mentions having seen an ostrich lay a dog prostrate by a single backward

blow given with the foot; and as the bird is very finely balanced upon its centre of gravity, there is no question that, by swinging upon the one foot, and giving the whole momentum of its body to the delivery of the other, it can strike in a very serious manner. Cuvier mentions, after Pliny and his copyists, that the ostrich throws stones behind it in its flight, with as much velocity as if they were discharged from a sling. The same has been said of the common seal, and the fact of discharging the stones is most likely true of both animals, though the cause is the extremely rapid motion in the ostrich, and the slow and wriggling motion, though with powerful organs, in the seal. The error lies in the assumed intention of either the one animal or the other; for there is no reason to suppose that either has the slightest intention of assailing the enemy with this sort of stern battery. When the ostrich runs in stony places, it is quite natural to suppose that the velocity with which it springs forward with the foot as a fulcrum, will make the reaction of the foot project a loose pebble of considerable size with very great force, and of course the pebble thus unintentionally projected may sometimes take effect upon whatever is in pursuit of the ostrich, and thus have the appearance of having been aimed. There are many of the results of animal action which in this way are supposed to proceed from intention, and thus the conduct of animals is confounded with that of man, and the proper understanding of both is vitiated.

Ostriches have been long and generally stigmatised as very stupid animals; and when we consider the obtuseness of all their senses except that of sight, they may appear stupid, as compared with those animals which have all the senses in nearly equal perfection. The stupidity or the acuteness of an animal does not, however, depend upon the number of well-developed senses with which it is furnished, but upon the perfection of those which are essential to its natural modes of life; and as there happens to be no animal which can be fairly contrasted with the ostrich in this respect, it is impossible to come to any definite conclusion on the subject of its stupidity; and the story of its being stupid may be allowed to take its place very quietly in the same category as the alleged desertion of her eggs and young by the female. We often make strange mistakes as to the stupidity of animals; for the ass and the goose are proverbial in this respect, and yet within their proper spheres they are both very tractable and sagacious animals.

The cry of the ostrich is a loud and harsh one, though it is not very often heard; and those who profess to describe it are not quite agreed as to what sound it resembles the most. We find some resemblance between the ostrich and the goose in the sounds which they emit and the attitudes which they assume when danger is very near them. We might perhaps be prepared to look for this from a kind of analogy that subsists between them. They graze on different localities; but still, when in a state of nature, they are both grazing birds, and this is a similarity independently of the difference there may be in other respects; and hence we find that a male ostrich, excited by the near approach of danger, ruffles his feathers, and hisses much after the same fashion that a gander does; and when either of them strikes under this excitement, he strikes with the nail upon the tip of his bill.

The breeding of ostriches in their native plains is a subject upon which there is no little uncertainty

and difference of opinion. That the birds are very prolific, and that, like our common poultry, in their native jungles of the East they have no fixed season for breeding, appears to be well ascertained. It is equally well ascertained that the eggs are numerous, though what the number is is not determined; some say fifty, and some not half as many, while others again bring up the number to nearly a hundred. There are various circumstances which tend to embarrass this part of their history. Under many circumstances, the females are gregarious in the breeding time, and place their eggs so near to each other that those of several birds may often be considered as forming only one hatch. Another circumstance is that birds which produce many eggs in a hatch are subject to greater variations in the number than those which produce only a few. The heat too which prompts the bird to hatch, and stops the production of more eggs for the time, comes on with different degrees of rapidity according to circumstances, and this necessarily affects the numbers of the broods.

There is another circumstance in the matter, on which the professed authorities are not quite agreed; and that is, whether the males are monogamous, or each has a number of females. No mention is made by any writer, worthy of credit, of having seen battles of gallantry between male ostriches; and if we were to argue from the habits of most polygamous birds in general, we would consider the silence with regard to such battles as a proof of monogamy. There is, however, an argument on the other side. Most birds which pair strictly, and yet are social, as, for instance, the pigeons, have usually a small number of eggs in each hatch, as, for instance, one male and one female, whereas the eggs of polygamous birds are far more numerous. This is not universally the case, for rooks and many other birds are an exception to it; but it holds in the case of almost all birds which are social in the breeding time, and deposit their eggs upon the ground.

It may seem singular that birds which have been for so long a period objects of great interest and inquiry, should have so many unsettled points in their domestic economy; but when we take into consideration the watchful look of the birds, the extensive horizon which they command, and the impossibility of getting a clear view of them in the natural state without depriving them of life, we find a sufficient explanation of these uncertainties.

The eggs, with the shells of which many must be familiar, are sufficiently large for containing a pint or more. They are of a dull white colour, with yellowish or brownish mottlings, varying a good deal in tint with the state of the atmosphere at the time of their production. They are not always of the same size, but vary in this respect like the eggs of poultry; and it is not understood that the largest-sized birds produce the largest eggs in the one case any more than in the other. They are seldom less than between five and six inches in the longest diameter; and they rarely, if ever, amount to so much as seven.

These birds do not, under any circumstances, construct a regular nest, or seek the cover of tall vegetation for the purpose of concealing their eggs. They merely scrape a very shallow space in the dry sand; and as the eggs themselves approach closely in colour to the sand itself, and to such pebbles as are usually found upon it, they are probably more safe from destroyers, in the absence of the female, than they would be in a formal nest. This seems to be the

provision which nature has made for protecting the eggs of most animals which breed on the ground. There is no parade of a nest, and the eggs so much resemble in colour the surface around them, that even on the dry sand of a sea-beach it is very possible that the first notice one has of them may be the sound of breaking them under the foot.

The time required for hatching the eggs of the ostrich is not known with any degree of accuracy, though it has been said that it requires between forty and fifty days, and rather more in moderate climates, and when the weather is wet, than in the dry heat on the margins of the desert. That it must require a considerable time is obvious, on account of the size of the egg and the hardness of the shell, and also of the degree of maturity at which the young have arrived when they make their appearance. Other circumstances being similar, eggs are the sooner hatched the less perfectly developed the young are when they break the shell. The shortest incubations are those in which the young birds appear quite naked, and incapable of using either the feet or the wings; and it is worthy of remark, that warm nests are always provided for birds of this kind; and they of course require to be fed by the parent birds for a much longer time than those which are more matured on their first appearance. Where the young come into the world in this comparatively rudimental state, two portions of the labour of the parent birds are greater than in other cases, namely, the construction of the nest and the feeding of the young. The abridgment of the time of sitting is, however, some compensation for this; and the warm nest no doubt tends to this abridgment.

There are other circumstances connected with those birds which have callow young, which are worthy of attention. In the first place, they are almost all small birds; for the large ones, almost without exception, have rude nests, or no nests at all; and their young are covered with down or with feathers at the time of their exclusion; and in every instance they are then capable of using their feet, while many of them can immediately find their own food, independently of the mother. In the second place, the birds under consideration generally have their nests where food is abundant, as in woods, thickets, hedges, and other rich places, where insects and other small animals are abundant; and the young are exclusively, in most of the species, and in the greater part in all of them, fed upon those animal substances. Thirdly, the season of the year at which those birds have their young in the nest is the season in which the larvae of insects come upon vegetation, upon that of the sweet-juiced trees especially, in those myriads, and with that voracious appetite, which would actually destroy the vegetation of the year, were it not for the countless thousands which those birds consume for their own food and for that of their young. We see, therefore, how finely the economy of these birds is adapted for the general good of the whole system of nature. It may seem that rooks, and many of the larger omnivorous birds which build nests in trees, form an exception to what has been stated. But their nests, though they often require a good deal of labour in the construction, and though the young are fed in them for a considerable time, are never so elaborate or so warm as those of the small birds. The habits of the birds too are intermediate. Their charge is the ground larvæ and other small animals, and the

eggs of other birds; and this intermediate sort of occupation corresponds with the intermediate style of the economy of their nests.

Many of the birds which build no regular nests, and whose young appear in an advanced state, are to a certain extent omnivorous; and many of them feed chiefly upon small ground animals. There is, however, in all cases a great degree of labour requisite for the finding of their food; and their exemption from the labour of nest-building, and that of bringing food for their nestlings, is the compensation which nature allows them for the severe task imposed upon them in supporting themselves individually.

As the ostrich constructs no nest whatever, and is in some places in a great measure exempted from the labour of incubation, we might naturally expect that the young should be provided for in the egg, until, under average circumstances, they should be able to find their own food when they come out of it. This is found to be the case, and not only so, but there is a very remarkable correspondence between the labour of incubation, which the female ostrich performs, and the care she takes of her young after they make their appearance. If she requires to sit little or none, then she abandons the young, and leaves them to provide for themselves; but if she requires to sit pretty constantly, she takes them under her protection, leads them to their pastures, and guards and defends them with as much boldness and solicitude as a common domestic hen. Thus, in the temperate climate of the Cape, and especially during the rainy season, which is the season of food, and therefore the season of reproduction for the ostriches there, the female bird is an attentive mother; whereas, on the burning sands nearer the equator, she pays little or no attention to her offspring. Whether, under these different circumstances, there is any difference of maturity in the young is a fact upon which we have no direct information; but the analogy would lead us to suppose that such a difference really exists. In that part of it which our information does reach, we have a striking instance of the modification of the same bird, so as to adapt it to differences of external circumstances. Where the ostrich sits closely and tends her young assiduously, there is an abundant supply of food for both, and they can satisfy themselves with comparatively little labour. It is then too that the young stand in need of protection, because the same richness of the pastures which feeds the ostriches feeds their enemies, if not directly, at least through the medium of the herbivorous mammalia. In the burning deserts again, where the labour is great, the ostriches are in a great measure alone; and, though the labour of finding their food is great, they are exempt from the danger of almost every enemy.

We have entered somewhat largely into those points of the economy of ostriches for various reasons. First, because the birds are in themselves among the most interesting, not of the feathered race merely, but of all animals; secondly, because those points have been slightly touched upon by some, and much misrepresented by others; and thirdly, because, from their geographical position, the ostriches may be said to occupy the centre or extreme place of the sun's action upon the earth; and therefore their history well understood may be made a most extensive and valuable index to the general economy of nature on the surface of our globe.

We have already alluded to the locomotive powers

of the ostrich as being very great. On its rapid marches it always extends the wings, the loose and flocculent plumes of which take a hold on the air, and prevent that swinging from side to side of the axis of the body, which would otherwise result from the motion of a long bodied animal with the axis horizontal, and upon two legs only. Those produced plumes, both of the wings and of the tail, perform an office not dissimilar to that which is performed by the swimming paws of the aquatic mammalia. The mode of action and the kind of organ are of course different, because the one animal moves through the air, and the other through the water; but making this allowance, and considering that the organ of progressive motion is a pair of legs in the land animal, and a swimming tail in the aquatic one, there is no inconsiderable resemblance between the two.

When the ostrich is in vigorous health, and unincumbered by any load, it is said to outstrip the very swiftest of four-footed animals, provided they follow its track, and do not cross it on the returns of its loops, as is done by the ostrich-hunters, whether mounted on horseback only, or accompanied by greyhounds. It is further said, that, with the load of two men on its back, an ostrich can run as fleetly as a good saddle-horse at full speed. Adanson, in his account of Senegal, mentions having seen this repeatedly; but we are not aware that it has been verified by the observation of more recent describers. From their disposition to be social in the wild state, ostriches may be expected to be susceptible of domestication; and if they could be domesticated, their great strength, great swiftness, and great powers of endurance, would render them very valuable labourers, especially as carriers on long journeys across the deserts. Their economy in wild nature, and also their haunts, are, however, different from anything which could be either readily or generally obtained in an artificial state, even within the geographical limits of the birds; and though they are far from being exclusively tropical in their localities, we have no reason to suppose that domestication could temper their nature to the endurance of the winters of middle, or even of southern Europe, if exposed to the open air. They have been so far domesticated in climates suited to their nature, as to be kept in flocks within enclosures; and as they cannot fly, of course hedges or walls are quite adequate to keep them in. Some of the boors or farmers at the Cape, living toward the interior of the country, have at times paid a little attention to the partial taming of ostriches, and have found it not difficult to reduce them to such a state of domestication, or rather endurance of the vicinity of man, as that they go about the farms without attempting to desert permanently to the uninhabited deserts. Hitherto, however, they have been objects of curiosity, and not of advantage, for they have been turned to no useful purpose; and their voracity and strength are so great, that, though splendid ornaments certainly, they are very expensive ones. In farm-yards they are said to be absolutely destructive, by trampling to death the ducks and common poultry with their great and heavy feet, and also by swallowing the young. That they do the latter from any carnivorous instinct is by no means probable; for, if true, it seems rather to be a part of that instinct which they have of indiscriminately swallowing all kinds of substances, nutritious, indifferent, and poisonous. If the strength of the

ostrich has not been turned to much account in the way of service, the flesh and the eggs have been turned to little more as articles of food. It is true that the Romans, in the days of that depraved and ridiculous luxury which finally converted the rulers of the world into the meanest and most contemptible of its slaves, introduced certain parts of the ostrich at their feasts. Heliogabalus is mentioned as having had the brains of six hundred ostriches cooked for a single feast. In the judgment of reason this can be looked upon as no other than a most profligate waste, something similar to the dissolving of pearls in beverages, where a pinch of chalk and a little bit of calf's-foot jelly would have had the same effect. When, however, we call to mind the prejudice which at that time set the ostrich down as the special emblem of stupidity, it is impossible to avoid admiring the admirable tact with which this imperial, but foolish glutton, suited his mess of ostriches' brains to the contents of his own cranium.

The plumes of the ostrich, though mere ornaments, are of more legitimate use. They have been sought after as ornaments from time immemorial, as we already hinted; and it should seem that there was early noticed in them the superiority of the living clothing of animals over the dead. It is well known that dead hair is very inferior, both in beauty and durability, to that which is obtained from the living subject. The same holds good in the feathers of the ostrich; those which are pulled from the living animal being far more beautiful, as well as durable, than those which are obtained from the dead one. It is to be understood, however, that the hair or feathers taken from an animal very recently killed is to be considered as living rather than as dead; for the durability of such hair or feathers is much greater than that of those which have been cast. Vast numbers of those feathers are sent to all the countries in the northern and middle latitudes, and, in short, to every part of the eastern continent where a native supply is not found from the bird itself. For the supply of the west of Europe those plumes are obtained, in great part, from the northern margin of the Great African Desert; and Mogador, in Morocco, is the chief part from which they are sent.

The skin of the ostrich is used as well as the feathers. It is exceedingly thick and tough, and employed in some of the southern countries for the same purposes as buff jackets were used at one time in Europe. It is formed into a sort of cuirass; and, as Butler says of the doublet of the redoubted hero of his matchless poem, it is,

"Though not sword, yet cudgel proof."

THE RHEA (*Rhea Americana*). This bird is usually styled the American ostrich, and it has sometimes been described as belonging to the same genus with the cassowary of the eastern isles, and again as of the same genus with the emu of New Holland. It is, however, perfectly distinct from both of these birds, as well as from the ostrich properly so called. Its characters are: the bill straight, short, soft, depressed at the base, and a little compressed at the point, which is obtuse, and furnished with a nail; the lower mandible is very much depressed, flexible, and rounded at the tip; the nasal grooves are very large, extending to the middle of the bill; the nostrils are on each side of the surface of the bill, cleft longitudinally, and open; the feet are long, very strong and robust, and they have three toes directed to the

front, the lateral ones equal to each other; the claws upon all the toes are of nearly equal length, rounded, compressed, and blunt; the tibia feathered down very nearly to the tarsal joint; and the wings, which are quite unfit for flight, are furnished with plumes of greater or less length, and terminated by a single spur.

As is the case with the ostrich of the eastern continent, there is only one species of this bird, and it is confined to a particular locality, though within the range of that locality it is far from being a rare bird. It is bluish ash-grey on the upper part; the crown and hind head are blackish; a black band begins at the nape, descends the lower part of the neck, which it surrounds, and gets broader on the shoulders; the scapular feathers are ash-coloured, and so are most of the plumes of the wings, but the larger ones are white at the base and blackish in the middle, and some of them are altogether white; the bill and feet are reddish grey; the height of the bird is an inch or two less than five feet, being thus considerably smaller than the ostrich.

This bird is quite unknown in the immediately tropical part of America, its principal locality being in the plains of Paraguay, and, where the ground is adapted for it, it is found in the elevated valleys among the Andes, and along the southern part of the continent as far as the Strait of Magellan. It must not be understood, however, that though the rhea is found in America in latitudes as high as the southern part of the British islands, it is in any way a bird of temperate climates; for, though the country which it inhabits is not very hot, still it is decidedly tropical in its vegetation, and in all its natural characters; and some species of humming birds extend at least as far southward as the rhea.

The extensive plains of the Pampas, to the south-westward of Buenos Ayres, are its head-quarters. Those plains are very peculiar in their seasonal character. For a short time, and but a short time, they are comparatively barren; but for the greater part of the year a luxuriant crop of thistles, and other *compositæ*, alternates with an equally luxuriant crop of clover, each one dying down, and furnishing a rich manure for the other. Human inhabitants are but few in those plains; but the birds under notice, and also wild cattle and horses, are exceedingly numerous. The cattle are very active, and the horses are swift; but it is doubtful whether the rheas are not fleetest of the three.

When tranquil, their gait is sober, their neck is elevated, and the back is curved. In grazing they cut the grass with much neatness. The time of reproduction is in the month of July; and at this season the males send forth cries similar to the lowing of cattle. They form the nest on the ground; it is rather wide, very shallow, and sometimes lined with a little straw. The eggs are between five and six inches in diameter, of equal proportions at both ends; their colour is yellowish white, and they are very smooth on the surface; and a single nest sometimes contains from sixty to eighty eggs. M. Azzara is of opinion that these are the production of many families of the same district; and he states, as an ascertained fact, that a single individual, said to be the male, hatches the eggs, and takes the charge of conducting and protecting the young. It is conjectured that the male selects some eggs from the others, and breaks them, in order that the insects which come to feed on the broken eggs may serve as food

for the young birds. But, though this is said, it is by no means probable; and indeed, in all the local accounts which are given of this bird, so much romance is mixed up with the truth, that it is extremely difficult to separate the one from the other. When the young birds are brought up in houses, they are very familiar; they soon become domesticated, and exhibit a great deal of curiosity in examining the different apartments. They also walk in the streets, and stray abroad to considerable distances from their habitations, but they generally return to the places where they are accustomed to be fed. They unhesitatingly swallow pieces of metal and small stones when these come in their way. In the young state the flesh is tender and tolerably well flavoured. Though these birds seem never to drink, they are not averse to take the water. They are excellent swimmers, and often traverse the rivers and lakes out of choice.

The skin of the rhea, like that of the ostrich, is very strong, and the inhabitants of those parts of South America in which the birds abound make use of it for a variety of purposes. The feathers of the wings are also used for ornaments, but they have neither the size nor the elegance of the corresponding feathers of the ostrich. Comparatively few of them are white, and even such as are, are by no means equal in colour to ostrich feathers. The taking of the birds, when nearly full grown, is a favourite sport with the Guachoes of the Pampas. They follow them on horseback, and, as the vegetation is then long, the horse gets on rather more swiftly than the bird. They are captured indifferently with the two instruments of which these people make such dexterous use—the *lasso* and the *bolas*. The lasso is a noose at the end of a long thong of leather; and it is delivered with such certainty, that the Guachoe, riding full speed, can catch the birds by the neck, the body, or the leg, just as he pleases. The bolas or balls, again, are of such weight, that the bird is knocked down by the blow of them.

OSTRYA (Michaux). A genus of hardy trees, natives of North America. The flowers are monœcious, and the genus is ranked among the *Amentaceæ*. These trees are common in our ornamental plantations, and known by the name of hop-hornbeam. They are raised from seeds or layers.

OSYRIDEÆ. A small natural order containing only two genera, viz., *Osyris* and *Exocarpos*, of each a single species. They are trees with flexile twigs, and from the acidity of the leaves the *Osyris* is called mountain sorrel, or poets' cassia. It is easily propagated by cuttings, but hardly hardy enough to stand our winters without covering. The *Osyris* of Pliny was a marvellous vegetable endowed with the property of curing every disease. But our modern *Osyris* cannot certainly be the plant which he describes, for, excepting a slight astringency, it possesses no sensible properties as a medicine, and is now only used for making besoms. *O. japonica* is occasionally eaten as a salad. *Exocarpos* has received its name from the enlarged receptacles on which the fruit is placed, giving the appearance of being a seed outside of its seed-vessel: a new species of *Exocarpos* is remarkable for bearing its flowers on the margins of dilated foliaceous branches, concerning which it would be difficult otherwise to determine whether they were boughs or leaves.

OTHONNA (Linnæus). A genus of very various

formed plants, some species being shrubs, others undershrubs, or herbaceous, with or without tuberous roots. They are natives of South Africa, and belong to *Compositæ*, are kept as green-house plants, and are easy of management, and propagated by cuttings.

OTTER. See LUTRA.

OURAPTERYX (Leach). A genus of lepidopterous insects, belonging to the family of nocturnal moths (*Geometridæ*), and distinguished by having the hinder wings furnished with a pair of short tails. The type is the swallow-tail moth (*O. sambucaria*), a handsome moth of a pale brimstone colour, about an inch and a half in expanse. It is not uncommon in the neighbourhood of London.

OUTEA (Aublet). A genus of shrubs and trees, natives of both Indies, otherwise called Joutay. They belong to *Leguminosæ*.

OVIS, a most important genus of ruminating mammalia, of which an account will be given in the article SHEEP.

OVULA (Lamarck; BULLA, Linnæus). Bruguière, in the first instance, separated the shells of this genus from those of the genus *Bulla* of Linnæus, with which they were confounded. Lamarck has properly adopted the same association of species, but has divided them into two families; the first consisting of those which have the right side of the aperture wrinkled, or thickened; and the second of such as are smooth on the right side; in which he includes the species having the last whorl attenuated, and producing long beaks or rostra at both ends of the shell, as in the *Ovula volva*, commonly called the weaver's shuttle. The genus *Ovula*, as it is now constituted, forms a very natural and well-defined association of species. Its rank in a system of malacology is immediately preceding the genus *Cypræa*, to which it may be considered nearly allied, as the animal differs in no essential characteristic. From the *Cowry* it may, however, be readily distinguished, no spire being formed, and both ends of the shell being continued in uniformity with each, or nearly so, in most species; and another striking distinction is, that the columella (lip) is never plaited, or, as it is sometimes called, toothed. To the genus *Bulla* they also approximate, being, like them, convolute shells; but the right lip, which is constantly folded, or reflected inwardly in adult shells, and either smooth or wrinkled, is a character quite opposite to that of the *Bulla*, in which the lip is straight. The form of the *Ovula* is ventricose like the *Cypræa*, oblong, oval, or sometimes egg-shaped; the whorls convolute, rolled upon their own axis, the outer one very considerably larger, and inclosing all the others; and in some species both extremities are prolonged, and form subcylindrical beaks, particularly in the *O. volva*, in which we have seen examples where this attenuated portion extended several inches from the central point of the whorls. In other species, as the *O. gibbosa*, the conformation of the whorls more nearly resembles that of the *Cypræa*, but they exhibit no spire; the edge of the right lip is always reflected inwards, and either smooth, or somewhat wrinkled; there are no columella plaits; the aperture is longitudinal, narrow, and extending the entire length of the shell; it is also effuse, without any operculum or epidermis. The mantle of the animal envelopes the shell completely, folding over by a continuation on one side; while in the *Cowry* it is expanded on both sides, and sometimes does not meet beyond a certain

point, which may be traced in some cases. In a young state the lip is sharp, but at an adult age it turns inwardly. This genus is the first of the six genera into which Lamarck has divided the shells, being spirally evolved on their own axis, viz. *Ovula*, *Cypræa*, *Terebellum*, *Ancillaria*, *Oliva*, and *Conus*. The two first only have their lip reflected inwards. This genus is beautifully figured in a Monograph published by Mr. Gray, F.R.S., to which we refer our readers. These molluscs mostly inhabit the Indian seas and those of the torrid zone. Some species are known in a fossil state. The animal is ably figured by Messrs. Quoy and Gaimard in the Atlas of Plates to their Voyages.

OWL (*Strix*, or perhaps rather *Strigida*, the owl family), the common name of all the nocturnal birds of prey. These birds are found in every country; and, though all of them are nocturnal, or rather crepuscular in their feeding, yet they are among the most laborious of birds; and the quantity of food which they consume in proportion to the weight of their bodies, is probably greater than that consumed by any other birds. As is the case with the diurnal birds of prey, taking them in the order of their disposition to prey upon the living bodies of warm-blooded animals, so, in the owls, the head-quarters may be said to be in northerly and cold climates. In tropical countries, indeed, there are plenty of owls, but they are not birds of so bold a character as the owls of the north, just as the vultures of the same countries are not so bold birds as the northern eagles.

There is a very singular adaptation of twilight and twilight bird in this geographical distribution of the owls, and, if properly followed out, it is one which is calculated to throw no small light upon the mode in which all the parts of nature are fitted to each other. In the tropical country the twilight is very short, nearly of the same length all the year round, and under the equator itself there is only about an hour and twelve minutes between sunset and absolute night. In the polar regions again, and even in temperate latitudes, the twilight is much longer. At the poles there is light all night for a part of the year, and bright twilight for a still greater part. Upon a Shetland hill one can read the smallest print with ease at midnight in summer, with fully more ease indeed than it can be read at mid-day in winter if the sky happens to be cloudy. Over all the northern parts of the island of Great Britain, it is pleasant walking light the whole night long; and Nature's night is so short, that hardly have the bitterns and other evening birds ceased to deliver their notes, when the birds of the morning are astir, and pouring forth their morning songs. There is a great difference between those morning songs and the evening notes of the birds; all the latter are harsh and jarring, and there is a monotony in the jar that tends to lull one asleep, in the same manner as is done by the trickling drops in a dripping cave, or the ticking of a clock. The morning song again, whatever be its pitch, is lively and inspiring, and tends to shake off that sleep which the evening song produces. It may be the cackle of the grouse, the whistle of the plover, the wail of the lapwing, or the glorious note of the lark showered down from the top of the sky, as if to call men to their labours; but, be it what it may, it comes thrilling over the mind like the spirit of the morning, and inspires freshness into such as happen to be abroad.

It would require more space than we can afford to analyse the relations which subsist between the notes of birds, the times at which they are heard, and the effects which they have upon the feelings, and consequently upon the actions, of the human race; but it is certain that this influence is very great, and, if investigated with due care, it would tend to throw much light upon the natural character of nations, especially of those nations which live within and near the icy zones, and whose character and feelings partake largely of that diversity which marks the seasons of the year. There seems little doubt that many of the birds which migrate northward in the early part of the season, help to lengthen the day to the human race. One loves to linger in the balmy air of a summer evening to hear the notes of the nightingale; and one is grateful for being awakened by the same when morning first dapples the east. Our present business, however, is more immediately with the owls, and to them we must confine the remainder of our observations.

Various writers on birds have divided the owls into genera or sub-genera, and described each division by certain characters, which chiefly consist in differences of size, and in the presence or the absence of produced feathers on the head, usually forming a sort of tufts, which have very absurdly obtained the name of horns. There is not much philosophy or use in those subdivisions; because, notwithstanding those differences in external appearance, an owl is an owl, whether it is large or small, and whether it has tufts of feathers on the head or not. If the same fondness for subdivision, and the same disposition to establish species upon small differences of external character which is often applied to the lower animals, were applied to the human race, where its application would be just as philosophical, we should often have three or four species of men in the very same family.

Such being the case, we shall merely mention the general characters of the owls as if they were but one genus, and shortly notice a few of the leading species of which this genus is composed. The first of these will enable us to convey a general notion of what is meant by an owl, and the second will equally enable us to point out in what manner and to what extent owls fitted for different situations and climates vary from each other.

The general characters are: the head large; the eyes very large, directed to the front, and covered by a circular concha or shell of feathers, the posterior margin of which covers the opening of the ear, and the anterior one the cere or naked skin at the base of the beak, and sometimes the beak itself. The irides of the eyes are remarkable for their sensibility. In the dark twilight, or when the bird is shaded, they are of immense extent; but when the light falls strongly upon them, they are so contracted as that no light is admitted, and the bird, unless in so far as it is guided by the sense of hearing, and the sensibility of its feathers, both of which are understood to be very considerable, is bewildered, flies bumping against obstacles, and would be an easy capture if it were worth the trouble. But an owl, though it looks plump in its feathers, is generally nothing but skin and bones in its body; and therefore it holds out but little temptation to those more powerful birds which are on the wing during the day. The skull of the owl is rather of large size, but of tender fabric, and a considerable part of it is taken

up by large cavities in which an expansion of the auditory nerve is inserted, and this no doubt tends greatly to increase the sense of hearing. The sense is indeed one upon which owls must in many situations have their principal dependence, notwithstanding the great volume of dim light which the expanded pupils of their eyes admit. This appears to be especially the case with those owls which hunt as they fly; and it is highly probable that the hunting alarms the prey, causes it to stir, so as to be audible, and thus contributes to the success of the hunting. Every one who has attended to the habits of animals must be aware that the cry of a predatory animal excites great agitation in its prey; and that, were not this the case, some of the most powerful of the predatory animals would possess their strength in vain.

Owls, for the most part, feed upon small mammalia, little birds and insects, which they generally catch upon the ground or in bushes; but there are some of the more powerful ones which prey upon grouse and other birds of considerable size, and capture them on the wing during the day.

Owls have the feet of nearly the same form with diurnal preys, namely, three toes in the front and one to the rear; they have very sharp and crooked claws upon all the toes, but these are not so thick and strong as in the diurnal preys. The tarsi are in general short, more slender than those of diurnal preys, but the muscles of the legs are well formed, and in general much protected by feathers. The bill is very crooked, though also much more slender than that of the diurnal birds. The muscles by which it is worked are also greatly protected from variations of temperature, by the produced feathers around the eye. Taking it altogether indeed, though an owl is much less formidably armed than a diurnal bird of prey, it is fully as ready in the use of those weapons which it does possess; and as we shall afterwards see noticed in some of the species, owls can endure a severity of climate before which the eagle herself is constrained to give way. This does not of course apply to all the species, for an owl, like every other creature, is endowed up to its necessity, but not beyond it; and in many countries the owls have no great variation of temperature to endure. As is the case with all animals which are naturally voracious feeders, owls can be tamed. In that state they are familiar, and learn to distinguish those who feed them, though they continue to snap and hiss at strangers. We shall quote a few observations on owls from "The feathered Tribes of the British Islands:"—"The very name of the owl," says the author, "is a name of lamentation, expressive of the sound of its note, which is one of the most melancholy love songs in the whole chorus of nature. Superstition has accordingly laid hold of the bird as one of the instruments by means of which to bind the ignorant in the fetters of fear; and the circumstances attendant upon the owl, although they admit of being turned to better and even delightful purposes, have certainly an aptitude to be so perverted.

"Deep shady groves, hollow trees, crumbling ruins clad with ivy, steeples and churches with their associations of graves and ghosts—all that seem dim to human reason, all that stand monumental of the works of nature, or of man and his works, is linked to the owl by the closest and most general associations. The owls in such places, often heard but seldom seen; when heard, heard in the gloom and stillness of night;

and when seen, appearing with something of judge-like solemnity—made them very readily convertible into a sort of doom-birds.

"The time of their appearance gave farther colour to the superstition. Gloomy days, when the congregated clouds hung low in the sky, but kept up by the strong resistance of the warm earth and the breezeless stillness of the summer air; murky days, when the sun 'was sick to dooms-day with eclipse,' all occasions when the heavens looked black upon the earth, but produced stillness rather than storm, borrowed the attributes of twilight, and so brought out the owl—brought it out by perfectly natural, and, according to the laws of its being, necessary causes, but causes which were not understood; and the event, being striking and mysterious, was remembered, all concomitant mishap was remembered along with it; so that the owl, which came out simply to see if there was 'a mouse stirring,' got the blame of the whole.

"But, notwithstanding, owls are interesting birds, and the sounds which they utter, though deep and monotonous, have music for a well-tuned ear, the part which they act in creation is, moreover, an important part; and from the numbers of vermin which they destroy, there are few birds more worthy of protection in an agricultural country than the owls. The Athenians made them sacred to their patron goddess for defending the labours of the loom; and if we cherished them about our farm-houses, they would do yeoman service in defence of the labours of the plough.

"Nor is the superstitious dread of them without its use, or would the abolition of them be unmixed gain. Mankind are all the better for some checks upon them at those times when they are not watched by their fellows; and the actual presence of the owl may have sometimes restrained the midnight plunderer from his purpose, as effectually as the mere thought of rural wisdom enwiggled with office. If so, and there is little doubt of it, the owl was a cheap policeman, keeping back one set of marauders, and exacting, as his fee, the destruction of another." Vol. I. p. 136-37.

We shall now advert to the principal species of the owls. Three of these are represented in the plate "OWLS;" and they may be considered as specimens of the owls of the cold, of the warm, and of the middle latitudes. The snowy owl, toward the reader's left hand, at the bottom of the plate, is the typical owl of the extreme north, and among the most formidable birds of the whole race. The one at the bottom, marked Egyptian owl, is from Africa, a country in which there are many owls, some of them imperfectly known. The Virginian owl, at the top of the plate, is a native of the central parts of North America, and it is a powerful bird. We may remark, in passing, that the owls of warm countries are, generally speaking, darker in their colours, more nocturnal in their habits, and have the feet less feathered than the owls of cold countries. The depth of the forests, in some of their haunts, answers nearly all the purposes of a twilight to them; and, as their pastures are richer than in the cold latitudes, they are less powerfully winged, and altogether birds of a softer description. Many of the arctic species are common to the two continents; or, at all events, if they are specifically different, the difference is so small, that, for popular purposes, it is hardly worth mentioning them. For this reason, we shall adopt

NAT. HIST.—VOL. III.

Wilson's descriptions of one or two of them; because his descriptions, when given from his own observation, never admit of improvement from anybody else.

THE GREAT WHITE, OR SNOWY OWL (*Strix nyctea*). This is what may properly be styled the monarch of all the owls; and, from its habitation, its powers of endurance, and its bravery, it is one of the most interesting of the feathered race. Its dwelling is in the extreme north, where it finds its food and rears its young among the rocky mountains and isles, despite all the violence of the northern storms. It is found in the north of Asia, in the north of Europe, and in the north of America; and it very rarely makes its appearance even in the most northerly of the Scottish islands, and rarely, indeed, on any part of the mainland, and never in the south. It is tempered to the "thick-ribbed ice;" and, when our navigators made their somewhat Quixotic expeditions in search of an *impassable* passage, from sea to sea, by the north end of America, they found this owl at the very extreme point which they reached, better fitted for the intensity of the climate, by the hand of nature, than they were by all the resources of their art.

Such a bird, found in such countries, is an object of great interest to every one who has the least feeling of nature; and, therefore, after we have copied Wilson's description of it, which is decidedly the best, we shall offer two or three remarks on its general economy.

"The male," says Wilson, "measures twenty-two inches and a half in length, and four feet six inches in breadth; head and neck nearly white, with a few spots of dull brown interspersed; eyes sunk deep, under projecting eyebrows, the plumage at their internal angles fluted, or pressed in, to admit of direct vision; below this it bristles up, covering nearly the whole bill; the irides are of the most brilliant golden yellow; and the countenance, from the proportionate smallness of the head, projection of the eyebrow, and concavity of the plumage at the angle of the eye, very different from that of any other of the genus; general colour of the body white, marked with lunated spots of pale brown above, and with semicircular dashes below; femoral feathers long, and legs covered, even over the claws, with long shaggy hair of a dirty white colour; the claws, when exposed, appear large, much hooked, of a black colour, and extremely sharp-pointed; back white; tail rounded at the end, white, slightly dotted with pale brown near the tips; wings, when closed, reach near the extremity of the tail; vent-feathers large, strong shafted, and extending also to the point of the tail; upper part of the breast and belly plain white; body very broad and flat. The female," continues the same admirable describer, "which measures two feet in length, and five feet two inches in extent, is covered more thickly with spots of a much darker colour than those of the male; the chin, throat, face, belly, and vent, are white; femoral feathers white, long, and shaggy, marked with a few heart-shaped spots of brown; legs covered to the claws with long white hairy down; rest of the plumage white, every feather spotted or barred with dark brown, largest on the wing-quills, where the brown margins are about two inches apart; fore part of the crown thickly marked with roundish black spots; tail crossed with bands of broad brownish spots; shafts of all the plumage white; bill and claws, as in the male, black;

A A

third and fourth wing-quill the longest ; span of the foot four inches."

Such is Wilson's description of the appearance of the birds ; but he adds an account of the eye, which is so circumstantial, and so eminently characteristic of the eyes of nocturnal birds, that we shall quote it in his own words :—" From the various individuals of these birds which I have examined, I have reason to believe that the male alone approaches nearly to white in the plumage, the female rarely, or never. The conformation of the eye of this bird forms a curious and interesting subject to the young anatomist. The globe of the eye is immovably fixed in its socket by a strong elastic hard cartilaginous case, in form of a truncated cone ; this case, being closely covered with a skin, appears at first to be of one continued piece ; but, on removing the exterior membrane, it is found to be formed of fifteen pieces, placed like the staves of a cask, overlapping a little at the base, or narrow end, and seems as if capable of being enlarged or contracted, perhaps by the muscular membrane with which they are encased. In five other different species of owls, which I have examined, I found nearly the same conformation of the organ, and exactly the same number of staves. The eye being thus fixed, these birds, as they view different objects, are always obliged to turn the head ; and nature has so exactly adapted their neck to this purpose, that they can, with ease, turn it round, without moving the body, in almost a complete circle."

A bird so furnished, by nature, in the warmth of its plumage, the power of its weapons of prehension, and its capacity of enduring such extremes of cold, is one of the best objects of study ; and it is impossible to form any correct idea of the character of this owl without a reference to the countries which it inhabits. In Europe it does not, as we have said, come far to the southward even in the severest weather. In America it ranges more extensively, finding its way not only to Canada, but into the middle states of America, and even sometimes much farther to the southward. The reason of this is the different character of winter in the two continents ; for, in America, what would be considered as severe enough for a polar winter, is met with as low down as the United States. This bird is, therefore, strictly speaking, a polar bird ; and it takes the lead among those owls which make the nearest approach to diurnal birds of prey, and which, for that reason, are sometimes called *falcon owls*. There are several others much smaller and feebler than this one, and they extend into the very warmest latitudes, the ones which haunt the low grounds there having the tarsi altogether, or nearly, bare of feathers.

Owls of this description are birds of the wilds, and of rocky places, rather than of woods ; they are swifter fliers, and more diurnal and given to hawking on the wing than the other owls. One can easily see why this can be the reason with this northern species. During a considerable part of the year there is perpetual sun on its pasture, and for a still greater part there is light the whole night over. The summer action of nature is extremely vigorous there ; vegetation sprouts, blossoms are expanded, and berries are ripened, as if it were by magic, while both the air and the waters swarm with insects and other small living productions of the season. These support the summer birds, which resort in vast numbers to the

north ; and this owl, in concert with the eagles and the more powerful hawks, is a regulator of the numbers of those birds. It must not be understood, however, that the long summer in those high latitudes is a season of atmospheric tranquillity. The places we allude to are, generally speaking, near the sea ; they are almost, without exception, hilly and rocky ; and in the heat of the season the currents keep the masses of ice in continual motion from place to place : there is, therefore, a great deal of evaporation, and condensation of humidity, alternating with each other, the result of which is dense fogs, which often come on very suddenly, and so close, that they put an end to the labours of diurnal birds of prey. At other seasons of the year the snow-storms are equally violent, and accompanied by winds which blow with the greatest fury, and attended with such thickness of drifting snow clouds, as to be proof against the eyes even of eagles, proverbial as they are for the keenness of their vision.

The autumn, and partially, also, what may be termed the spring, are the seasons of those storms, while the fogs are more frequent during the summer. Both kinds of weather are, however, well adapted to the habits of the snowy owl, which, clothed, armed, and protected as it is, pursues its course, and carries on its avocation, let the fog thicken and the snow drive as they may.

In the season of the fogs, and also in that of the autumnal storms, the snowy owl flies low, and feeds chiefly upon grouse, ptarmigan, and other ground birds, which it captures in great numbers, and gets exceedingly fat. It is so voracious, that it seizes prey indiscriminately on the land and the margin of the waters. Upon the moors its chief prey is the birds that we have noticed ; on the sandy islands it consists of rabbits ; and when it is absolutely frozen out from the land by heavy falls of snow, it repairs to the water and catches fish, for whose appearance within its reach it waits with all the patient gravity of a devoted angler. It even plays the vulture when occasion serves ; for, though carrion of any kind is not so plentiful in the polar latitudes as in the warmer ones, there are seasons at which it is rather abundant. Of the ground birds of the north, there are many which quit that part of the world with reluctance, and not till they are literally driven by the storms. Those storms are excessively violent ; and, as the snow thickens the air to dimmest twilight, the affrighted birds lose their way, and also all command of themselves, and vast numbers of them find their graves in the snow wreaths. Their bodies do not putrify there, but are preserved by the frost, until the returning sun of a new season melts away the annual mantle of the ground. Spoils of birds, and also of small quadrupeds, are then disclosed in considerable numbers ; and these furnish a supply for the snowy owls, and other predatory birds, until the summer tenants of the northern wilds make their appearance.

During the time that the country is completely sealed up with snow, and the greater part of nature slumbering in the unbroken serenity of winter, the supply of these birds is somewhat different. As every observer of nature in the snowy districts of Britain must have noticed, by the prints of little feet along the surface, the small rodentia of the wilds come upon the surface of the snow to seek the exposed bark of bushes, and other vegetable matters ; and it is on these rodentia that the more powerful

owls, and also the eagles of the north, contrive to feed while the snow remains unbroken.

The circumstances which we have mentioned will serve to point out in brief how these birds of the north support themselves at different seasons of the year; and it is impossible to avoid admiring what nature has made in them for preventing any part of the provision of the year from being lost.

The species of owl under notice is very seldom found where there are woods; and therefore its resting-place, and also its shelter, during those extremities of the storm, which even its mantle and wing are incapable of bearing, is in the clefts of the rocks. It is not much of a wanderer; and it is probable that the few which are seen in Orkney, and more frequently in Shetland, reside there all the year round; nor do the northern ones quit their snowy fastnesses until they are reduced to the greatest extremity. When they do, they are usually found upon the snow, or rather upon some jutting stone, or projecting stick, which rises above the surface; and as the bird and the snow do not differ much in colour, the small birds are not alarmed, and thus they are captured with comparative ease. We may add, that this owl, and the other owls which, like it, are of bold character, and prey on the wing, and have no tufts of feathers on the head, are not so much molested by flocks of small birds as the owls of more nocturnal characters are when they come abroad during the day.

Of the division of owls to which this belongs, namely those which have no crests on the head, no very produced feathers round the eye, and the tails of moderate length, we can only afford to give a mere list.

THE LITTLE OWL (*S. passerina*) is one of the most common of these, though as a British bird it is rather rare. It is about seven inches long, and twice as much in the stretch of the wings from tip to tip. It is thus a well-winged little bird, and it is as bold as it is powerful. It is found in America as well as in Europe, though its size in the former country is larger, and it is perhaps a little different in the colours. It is rather a woodland bird in America, frequenting the swampy shores and the margins of the waters. In Europe its habits are rather different; for it approaches the vicinity of houses, nestles in holes of walls, usually hides itself in them during the day, and comes abroad on its mousing excursions chiefly in the twilight. It is not, however, confined to that time of the day; for when the sky is gloomy, and the swallows are out in great numbers, it may sometimes be seen hawking after them with considerable dexterity and success. Swallows generally fly in curves; and the little owl, though not perhaps so swift naturally as they are, takes the chord of the arch, and not the arch itself, by which means it is enabled to come up with them. In America it is very common, extending even to the north parts of Canada, and building its nest in the dark and thick pines, not on the tops of the trees, but about midway. The nest contains two white eggs, as is the case with the whole of the genus; and in those parts of the world Wilson says it is rarely seen during the day, though exceedingly active after twilight closes in. Its colours are: olive brown on the upper part, with some white spots on the scapulars and coverts of the wings, and five bars of white passing obliquely over the first five primary quills; the tail is rounded,

rather darker than the body, tipped with white, and crossed by two rows of white spots; the inner webs of the wing feathers are also spotted with white; the ear coverts are yellowish brown; the crown of the head, the upper part of the neck, and a circle round the ears, olive brown, beautifully marked with white dots; the front pure white, but ending in long blackish hairs, and there is also a black spot radiating outwards at the inner canthus of each eye; the lower parts are ochre-yellow, streaked with reddish bay; the thighs and feathered parts of the legs, which extend down to the very claws, are pale buff; the irides are pale yellow, and the claws, which are long and very sharp pointed, are black. This is the description of the female bird, which, as is the case in all the species, is rather larger than the male; and the young male, being coloured like the female, and smaller in size, has sometimes been described as a different bird.

THE FEATHERY-FOOTED LITTLE OWL (*S. dasypus*) is rather larger than the one now mentioned. It is brown with white spots, larger on the under part than on the upper. The tarsi and toes are completely feathered. It is found occasionally in some parts of the south of England; but, comparatively speaking, it is a rare bird in this country.

The number of species or varieties described as belonging to this section of the owls is very great; and they are found in all countries, from the northern boundary of the temperate climates to considerably southward of the equator. A full description of all these species would fill an entire volume, and even then it would not be very satisfactory, as the species are not a little confused. Two of the smallest species are the occipital owl of Africa and the sparrow-like owl of Brazil. The first of these is brown, yellow, and white on the upper part, and whitish streaked with rust colour on the under. The front and top of the head are reddish white, mottled over with dots; and the quills are banded alternately with red and brown. The toes, as well as the tarsi, have a downy covering. The total length of the bird is about seven inches. The other species has the head greyish brown, with white dots; the scapulars and wings spotted and banded with white; the tail black, with four white bands; and the front, the throat, and the under part white. It is only six inches in length, and is one of the smallest of the owls, but a bold and active bird for its size. Some other owls, belonging to this division, and chiefly found in the tropical parts of America, have the tarsi naked, and the tail short; while those of the colder latitudes uniformly have the tarsi feathered. The whole of this division are to be considered as the most active and least nocturnal of the owls; and many of the small ones of the tropical countries are found flying about under the shade of the forests during the day as well as in the twilight.

Many owls of the same division have the tail considerably longer, and wedge-shaped. Of these, one of the most remarkable is,

THE HAWK OWL (*S. Hudsonia* of Wilson). This is very common about Hudson's Bay; but it is not very correctly named from that country, inasmuch as it occurs equally in the eastern continent. It may be regarded as being, in its locality, a borderer upon the country of the snowy owl of the extreme north. Like that owl, it extends further southward in America than it does in Europe and Asia; and in Europe it is rarely indeed to be met with to the southward

of the Baltic; nor is it at all common in the central states of the American Union.

It is a bold bird, active upon the wing, and among the most diurnal of all the owls; pursuing birds with great boldness in daylight, and sometimes snatching partridges and other game after they have been shot by the fowlers. It has, indeed, some of the characters of a hawk, resembling that species in the smallness of the head, the narrow feet, and the produced tail; but still its feet, and the feathering around its eyes and bill, bring it decidedly within the owl family. Still, however, its general plumage, and especially the plumage of its wings, differs much from that of the more characteristic owls. In them the quills of the wings have their external webs drawn out into a margin of hairs so fine and flexible, that the wing works noiselessly in the air, though of course it takes a hold on that element, which lessens the rate of flight in the bird. This owl wants the marginal fringe to the quills, and thus its flight is firmer, but more noisy. This agrees exactly with its habit, which is to dash boldly upon its prey and seize it on the wing; whereas the downy-winged owls come upon their prey by stealth, and always the more stealthily the more that their wings partake of this muffled or downy character. Wilson gives the following description of this bird as it occurs in the northern parts of the United States. "The male of the species is fifteen inches long; the bill orange-yellow, and almost hid among the feathers; plumage of the chin curving up over the under mandible; eyes bright orange; head small; face narrow, and with very little concavity; cheeks white; crown and hind head dusky black, thickly marked with round spots of white; sides of the neck marked with a large curving streak of brown black, with another a little behind it of a triangular form; back, scapulars, rump, and tail coverts brown olive, thickly speckled with broad spots of white; the tail extends three inches beyond the tips of the wings, is of a brown olive colour, and crossed with six or seven narrow bars of white, rounded at the end, and also tipped with white; the breast and chin are marked with a large spot of brown olive; upper part of the breast light; lower and all the parts below elegantly barred with dark brown and white; legs and feet covered to and below the claws with long whitish plumage, slightly yellow, and barred with fine lines of olive; claws horn colour. The weight of this bird was twelve ounces. The female is much darker above; the quills are nearly black; and the upper part of the breast is blotched with deep blackish brown."

Nearly allied to this species there are several others in different parts of the world, though none of them appear to be so well known as this one. There is one described by Pallas and others, as inhabiting the northern parts of the mountains of Ural, and other hilly districts lying on the margin of the Polar Sea. It approaches in size to the snowy owl; and it resembles it a little in colour, though the greater length of the tail prevents any danger of confounding the one with the other. The upper parts of it are whitish, marked with large longitudinal spots of brown. The head is large, and so is the face, which is much feathered, of a greyish white, surrounded with black hairs, and a circle of white and black. The quills and tail feathers are barred with alternate streaks of black and whitish. The under parts are whitish, with a brown streak down the middle of each feather. The

tail is wedge-shaped, and longer than the closed wings. The bill is yellow, almost entirely concealed by the hairs of the face. The irides are brown. The feet and toes are completely feathered, of a white colour, with brown spots. The claws are long, and of a yellow colour. The entire length of the full-grown bird is about two feet, which is intermediate between the male and female of the snowy owl; but as the tail is much longer than in that bird, the length of the body is less in proportion; and, altogether, the bird is not nearly so heavy. The young birds are differently coloured from the old ones, being mottled with brown, red, and white, and having cross bars of grey on the tail. In this plumage they have sometimes been described as a different species from the mature birds; but the identity has been established upon authority which cannot be questioned. Next to the snowy owl, this is one of the most powerful and vigorous birds of the division which prey on the wing, and occupies the same place among the long-tailed owls as the latter does among those which have the tail short.

Another species resembling this in some particulars is the hawk owl of Southern Africa. It is found in the district of the Cape; but it is a smaller and feebler bird than the northern species which we noticed last. On the upper part it is reddish grey, spotted with white, with spots of the same on the wing coverts and the tail feathers, with the exception of the two middle ones, which are grey. The upper parts are entirely white. The bill, which is very short, is black. The feet and toes, which are small and feeble, are entirely feathered. The tail is very long, and wedge-shaped; and the entire length of the bird is scarcely more than the half of that of the bird of the western mountains. Another African species is the variegated owl of authors, which differs from the one now mentioned chiefly in the colours of the plumage.

It would, however, be almost endless to mention the various owls of which this very numerous division is composed; but there is still one species which deserves notice from the peculiarity of its manners. This is the rabbit owl of Molina, improperly called the Coquimbo owl by Latham, inasmuch as it is found in North America as well as in South. The upper parts of it are varied with yellowish grey and brown, marked with brown spots of larger size. Two circles of white and grey surround the face, and a white band passes over the eyes. The flanks are reddish with brown spots; and the rest of the under part is whitish. The bill is greenish in the middle and blackish at the sides; and the feet, which are thinly covered with hairs, are grey. Its length is about nine or ten inches; it occurs chiefly on the dry plains of warm countries in America; and the chief peculiarity of its manners is, its digging a burrow for itself to the depth of a few feet in the earth, after the manner of a rabbit. Its eggs are represented, contrary to the habit of most of the owls, to amount to not less than a dozen, of a white colour, and nearly round in shape.

The species which we have noticed do not amount to nearly half of the owls of this division which are named in collections; but so little is known of the manners of these, and indeed of the greater part of those which we have enumerated, that little or no information respecting them can be given which would in the least interest the general reader. We shall,

Virginian Eagle Owl.

Snowy Owl

therefore, proceed to the next division or section, which approaches most nearly to this one in numbers, which is more nocturnal than this division, and in which the heads of all the species are marked with tufts of hair or feathers, varying in length in the different species, and in some of them bearing a slight resemblance in external shape to the ears of a cat. It is distinctly to be understood, however, that these tufts are not ears in any one case, any more than they are horns, for there is no projection of the skull or of the skin answering.

THE GREAT TUFTED OWL, OR EAGLE-OWL (*S. bubo*) holds nearly the same rank, and also the same geographical place among the owls with produced feathers on the head, and large discs of feathers surrounding the eyes, as the snowy owl does among those which are without these appendages. Like that species, it is decidedly a bird of prey, levying very large contributions upon game and other birds, as well as upon hares, rabbits, and other small and feeble mammalia.

As is the case with the other two, it is found in both continents, or, at all events, the species met with in America, and that met with in the east, so nearly resemble each other, in size, colour, and habits, that a single description will serve quite well for the two. This owl abounds in some places pretty far to the north; but it is not decidedly an arctic bird, like the snowy owl. In Europe it is more abundant in the north, on the mountains, and in the mountain forests of Lapland and Russia, than it is in coming farther to the south. It is found, however, in countries pretty far south; and as it is a bird which dashes about with bold and powerful wing, it may sometimes pass into Africa in the course of its migrations, reaching the mountains of Atlas from the mountains of Spain, as is the case with several birds of cold climates. In the mountains of western Asia, it most likely extends seasonally along the Caucasus and adjoining mountains; and it has certainly been seen as far southward as the confluence of the Volga with the Caspian.

In America it is resident in every part of the United States, where its manners, or at all events its haunts, appear to be a little different from what they appear to be in the east. The dark and dense forests among the swamps are its favourite residence, in which it remains silent for the day, but utters very loud and dismal cries during the night. This part of its character cannot be better described than in the words of its American historian. "This noted and formidable owl," says Wilson, "is found in almost every quarter of the United States. His favourite residence, however, is in the dark solitudes of deep swamps, covered with a growth of gigantic timber; and here, as soon as evening draws on, and mankind retire to rest, he sends forth such sounds as seem scarcely to belong to this world, startling the solitary pilgrim as he slumbers by his forest fire,

'Making night hideous.'

Along the mountainous shores of the Ohio, and among the deep forests of Indiana, alone, and reposing in the woods, this ghostly watchman has frequently warned me of the approach of morning, and amused me with his singular exclamations—sometimes sweeping down and around my fire, uttering a loud and sudden, Waugh O! Waugh O! sufficient to have alarmed a whole garrison. He has other

nocturnal solos, no less melodious, one of which very much resembles the half-suppressed screams of a person suffocating, or throttled, and cannot fail of being extremely entertaining to a lonely benighted traveller, in the midst of an Indian wilderness."

Young birds, squirrels, rabbits, rats, mice, partridges, and different kinds of small birds, are its principal prey; and in proof of its voracity in devouring these, we may relate the following anecdote from Wilson:—"A very large one, wing-broken, while on a foraging excursion, was kept about a farm-house for several days, and at length disappeared for several days, no one knew how. Almost every day after this, hens and chickens also disappeared, one by one, in an unaccountable manner, till, in eight or ten days, very few were left remaining. The fox, the minx, and the weasel, were alternately the reputed authors of this mischief, until one morning the old lady herself, rising before day to bake, in passing towards the oven, surprised her late prisoner, the owl, regaling himself on the body of a newly-killed hen! The thief instantly made for his hole, under the house, from whence the enraged matron soon dislodged him, with the brush-handle, and without mercy despatched him. In this snug retreat were found the greater part of the feathers and many large fragments of her whole family of chickens."

These birds are not migratory in the United States, but remain in the country all the year round; and as there is a bird very much resembling this in Mexico, which is also resident there, they have been described as two different species, and neither of them the same as the European one. The one of the United States has the crest, and also the markings somewhat different from the European one, but it is very doubtful whether these differences be anything more than climatal; and this is probably the real cause of difference between those animals of the two continents, which resemble each other in their general characters. The American one has the tufts longer and broader than the European; but as we are quite ignorant of the use of those tufts in the economy of the birds, we have no clue whatever to the climatal course by which their form or size may be modified.

In Europe the bird is more migratory, which is not exactly in accordance with the general habits of birds in the two continents. It is chiefly in the north in the berry season; and it very rarely comes to any part of the British islands, excepting Shetland, Orkney, and the extreme north of Scotland. Sometimes, however, it does visit the English shores; and when it does so, it is either to the northward of Flamborough Head, or to the southward of the Thames, as the line of the coast in both these places is most likely to intercept a heavy bird when migrating southward, and beaten from the direct line of its migration by the north-east wind. It is not a little remarkable that, while the birds which migrate from the north most frequently take the English coast at one or other of the places we have named, those of the eastern migration more frequently land on that portion of the coast which lies between these.

When this singular bird, for both its appearance and its voice are singular, visits a strange country, and flies by day, as it often does, it seems to strike kites, crows, and other wing birds with perfect astonishment; for they appear to descend and crowd about it for no other purpose than that of wondering at it. This tendency which other birds have to be

attracted by it is sometimes turned to considerable account; for the keepers of preserves of pheasants and other game occasionally display it in confinement, to attract other destroyers of birds and eggs.

When it migrates to a distance, it gets into lofty flight; but when it preys its flight is low, and its note is deep and dismal. By means of this note, it is understood to alarm the birds and other animals upon which it preys, to such an extent as to make them disclose themselves victims to its rapacity. That rapacity is very great; and, in the nesting time especially, the quantity of prey which these birds consume is immense. All owls are, indeed, ravenous and frequent feeders; and as the young remain longer in the nest than those of very many birds, they lay a heavy contribution upon such animals as serve them for food. Under some circumstances this may be an evil; but if we consider that these owls chiefly resort to the wilds of nature, the probability is that the good which they do may predominate upon the whole. Some countries are so completely overrun by small ground rodentia, that when these descend from the mountains they would produce desolation were it not that such birds as the eagle-owl accompany them and thin their numbers. In Norway this is especially the case with the lemmings. In ordinary seasons these little animals keep in the forests the whole year round; but they sometimes invade the plains like a torrent; and when this is the case, the eagle-owls are of great service to the people, from the great numbers that they destroy. These owls are therefore looked upon with great favour by the people of that country; and it is possible that the mythological favour bestowed upon owls in general, as birds of wisdom, arose in a great measure from their service in the destruction of small mammalia. We need hardly mention that an owl of some species or other, perhaps the little owl of the south, which has only a few hairs on the feet, was the bird of Minerva; and there are some singular attentions paid to the owl, or, at all events, to the spoils of it, by some of the tribes of American Indians, which have a singular coincidence with the favour shown to the birds in ancient mythology. "Among the Greeks," says Bartram in his Travels, "the junior priests or students constantly wear a white mantle, and have a great owl-skin cased and stuffed very ingeniously, so well executed, as almost to appear like the living bird, having large sparkling glass beads, or buttons, fixed in the head for eyes. This insignia of wisdom and divination they wear sometimes as a crest on the top of the head; at other times the image sits on the arm or is borne on the hand. These bachelors are also distinguished from other people by their taciturnity, grave and solemn countenance, dignified step, and singing to themselves songs or hymns in a low sweet voice as they stroll about the town."

In Europe, the eagle-owls construct large nests in lofty trees or in rocks, but the eggs seldom exceed two in number. The American ones generally build in trees; and in the United States they do not begin till the month of May. The nest is usually placed against the fork of a tree; but if there is a hollow at a sufficient elevation, the preference is given to that as requiring less labour in building. The eggs are described as being four in number, of a pure white colour, nearly as large as the eggs of a common fowl, and round. The spoils of a number of birds are generally found in the nest after the young have quitted it.

The colours of those formidable owls are various shades of brown, tawny, and rust colour; and the male has some white on the breast, while the upper colours are brighter than those of the female. Taking it altogether, and whether we regard it as consisting of a single species varied by climate and locality, or several species in the different countries where it is found, the eagle-owl is one of the most interesting of all the owls; and from the powers with which it is endowed, and the extent over which it is distributed, there is little doubt that its use in the economy of wild nature is very important, though it is not much wanted in countries where the surface generally is cultivated by man.

LONG-TUFTED OWL (*S. otis*). This is a resident owl in the British islands, and one of the finest in the country. It is not so common, or, at all events, so frequently seen as our native tuftless owls; though the latter circumstance at least is a good deal owing to its less familiar habit. It is strictly a woodland bird, and loves the shade at all seasons of the year, and thus it is most abundant in evergreen forests, though these conduce to its concealment. But though a woodland bird, it is not a mountaineer. It is never found beating over the upland and exposed moors, nor does it haunt the woods of the high glens. It is thus a bird of very different character, not only from the smooth-headed owls of the polar regions, but from the eagle-owl. Accordingly it is not found far to the north, and may be considered as a bird of Middle Europe. It also occurs in the American continent, chiefly in the thick forests over the swamps.

It is a bird of moderate size, the female measuring about one foot three inches in length, and three feet four in the stretch of the expanded wings. It is thus a well-winged bird for its size, and consequently a powerful flyer, though, as we have said, its range of flight is within the forests. When it flies its wings are very noiseless, and it glides along with little apparent resistance from the air. The ground colours of the plumage are rich, and the markings beautifully diversified. The upper part is orange, marked with black streaks, and finely sprinkled with delicate touches of black, grey, and white, becoming paler in the shades towards the sides, and thus giving a very pleasing relief to each feather. The under part is buff colour, marked with lines and arrow-head spots, something like the markings upon several of the diurnal birds of prey. The quills of the wings are brownish-orange, crossed by bands of blackish-brown; and the tail feathers are grey-orange, barred and spotted with black. The feathers of the tarsi and toes are the same as the ground colour of the tail, and without any markings. The tufts, which the bird can move at pleasure, are about an inch long each, composed of a variable number of feathers. The eyes are very bright reddish-orange; and the large conchæ with which they are surrounded give them a very fiery and formidable aspect when the bird glares with them from the deep shade.

The female is the more interesting bird of the two, as will be explained when we come to speak of her nesting habits. She differs a little from the male; and as the young of these owls are in considerable request with those who are fond of birds, we shall add the description of her. The tufts larger than the male, the front feather in each being the shortest, and the others gradually increasing in length backwards.

Their colours are black at the bases and in the middle, and dull yellow at the edges. The irides are vivid yellow; the inside of the circle of the face is white, and the cheeks are of a rusty colour. At the internal angle of the eye there is a streak of black; the bill is blackish horn-colour; the forehead and crown are dark brown, speckled with minute spots of white and pale rusty colour; the outside circle of the face is black, and finely marked with small curving white spots; the back and wings are dark brown, sprinkled and spotted with white, pale, ferruginous, and dusky; and the primaries are barred with brownish-yellow and dusky, darkening towards the extremities; the secondaries are more elegantly barred, and sprinkled with similar markings; the tail is of the same length as the wings, rounded at the extremity, and finely barred and marbled with dull white and pale rust-colour on a deep brown ground; the breast and throat are beautifully clouded with cream, black, white, and rusty; and the belly is finely streaked with large arrow-heads of black; the thighs and legs are plain pale rust, feathered to the claws, which are large and sharp, and of a blue-black colour; the insides of the wings are brownish-yellow, and there is a large spot of black at the root of the first quills.

Both in the old continent and in America these birds are fond of possessing themselves of the nests of others. It is only in particular situations that they dispossess the common rook, because the nests of rooks are usually too much exposed for suiting the habits of the owls. The magpie has its nest in places of greater concealment than the rook; and, therefore, though it makes a little show of fight, and a vast deal of chattering, it must sometimes resign its castle to the more powerful arms of its downy invader. Wilson found one that had taken possession of the nest of a night heron in a swamp near Philadelphia; but, after it had once taken possession, it does not appear to have offered much violence to the noisy colony, for a night heron continued to sit in another nest upon the same tree. In many places this conduct of the long-tufted owl is quite harmless to the other birds, inasmuch as their young have quitted the nest before it comes to take possession. The average of the eggs is about four, and never more than six; they are perfectly white, and nearly spherical. The young remain a long time in the nest; and, for some time after they have quitted it, they continue on the branches, so that the finding of food for them is a great labour to the parent birds. They very early evince a pugnacious disposition, by hissing and snapping with the beak, ruffling the feathers, and making themselves as ugly as possible. The old ones are also pugnacious; and, if their wings are crippled, they throw themselves on the back, and fight stoutly with beak and claws.

THE BARRED OWL (*S. nebulosa*) is an American species, bearing some slight resemblance to the one last mentioned, only it is without tufts on the head, differs in colour, and approaches in many respects to the hawk-owls. They nestle in trees, though not so much in the depth of the forests as the tufted owls. They are consequently more seen, and probably also more numerous. Their nests are rudely built of sticks, and concealed among thick foliage. Their eggs are large, and, like the rest, white. The female bird differs more in size from the male than in most species of animals, being sometimes nearly one half longer. These are more diurnal than the tufted

owls, often flying about during the day, and uttering a cry resembling that of the hawk. They sometimes seize partridges and young rabbits; but mice are their staple supply, and in the capture of these they render some service to the farmers. The male bird is described as being about sixteen inches in length, and thirty in the stretch of the wings. The upper parts of the body are of a pale brown colour, spotted with transverse markings of white; the wings are crossed with alternate bars of pale brown, rather darker in tint than the upper parts; the head is very large, smooth, and mottled with spots of white, dark, and pale brown, which extend transversely; the eyes are dark blue, large, and the pupil is not visible; the face, or radiated circle of the eyes, is grey, encircled by a margin of white and brown spots; the bill is of a yellow ground, tinged with green; and the breast is transversely barred with brown and white bands; long streaks of brown, on a yellowish ground, extend lengthwise along the belly; the vent is yellowish white, and the thighs and legs are of the same colour, and feathered nearly to the claws, which are remarkably sharp, and of a dark horn-colour; the tail is rounded, crossed with six broad bars of brown, and a like number of narrow white, and curved below; the back and shoulders are of a chestnut colour; at each angle of the eye there is a broad speck of black; long black hairs terminate the plumage of the radiated circle round the eye; and the bill is surrounded by others of a more bristly texture. The female bird is about twenty-two inches long, and four feet in the stretch of the wings. The chief difference in colour from the male bird is, purer brown on the scapulars, more white on the wings; the tail is also longer, the bill much larger, and of a finer yellow. In treating of this species, Wilson gives so beautiful a description of the various feathers upon owls, that it ought to be known by every reader, now that the observation of birds, in a state of nature, has become so very general. "The different character of the feathers of this, and, I believe, of most owls," says Wilson, "is really surprising. Those that surround the bill differ little from the bristles; those that surround the region of the eye are exceedingly open and unwebbed; these are bounded by another set, generally proceeding from the external edge of the ear, of a most peculiar small, narrow, velvety kind, whose fibres are so exquisitely fine as to be invisible to the naked eye; above, the plumage has one general character at the surface, calculated to repel rain and moisture; but, towards the roots, it is of the most soft, loose, and downy substance in nature, so much so, that it may be touched without being felt; the webs of the wing-quills are also of a delicate softness, covered with an almost imperceptible hair, and edged with a loose silky down, so that the owner passes through the air without interrupting the most profound silence."

THE SHORT-TUFTED OWL (*S. brachyotos*). This species is very different in its characters from the long-tufted one, and also from the barred owl of America; and it follows more on the character of the eagle-owl, though it is not near so large, nor quite so northerly in its geographical position. Its plumage altogether is shorter and firmer than that of the others, and it is weightier in proportion to its size. It is found on both continents, though perhaps, as is usual, it differs a little in colour, and it is more a woodland bird in America than in the east. This,

by the way, is a difference in character between very many of the birds of the two continents, as, that which is a field-bird in Europe is a forest-bird on the other side of the Atlantic. But this is a matter of necessity, not of choice; because North America was originally almost wholly a wooded country, and it remains so to a very great extent still. As a British bird, it rarely, if ever, nestles except in the extreme north, principally in heaths and tufts of grass. It also lodges in such places; and, when driven from its lodgment during the day, it flies to a short distance, and then alights, turns round, and reconnoitres the disturber, with apparent astonishment that the *siesta* of so sage a bird should be interrupted in so daring a manner. In winter it often ranges to the southward, and, contrary to the habits of most owls, it is found in flocks, as Bewick mentions, twenty-eight being seen in one corn-field in the month of November. As compared with most owls that come into temperate latitudes, it is a sturdy and stern bird, looks with great gravity, and catches mice with much dexterity. When it is in a state of complete repose its tufts are not observed, but it erects them when its attention is excited. These tufts consist of very few feathers, and are not perceptible on the dead bird without very close examination. When the weather is clear, it remains concealed in a tuft, or perched on a stump, watching for whatever prey may come within its reach; but, when the weather is very dark, it flies out, though by very short flights at a time. On such occasions it gives chase to any bird that may happen to rise; and it is highly probable that, in the moors, it feeds a good deal upon ground birds and their young. Mice are, however, its principal food, especially in rich places and the neighbourhood of thickets; and its vigilance and strength are such that it captures great numbers. The length of the male is fifteen inches, and the stretch of the wings about three feet four inches. The general colour of the upper part of the body is dark brown, and the plumage is broadly margined with pale yellowish brown; the irides are rich golden yellow, embedded in a border of deep black, which radiates outwards at all points except towards the bill; here the plumage assumes a whitish colour; the bill is large, and of a black colour; the ears are margined with a semicircular streak of black and tawny yellow spots; the tail is rounded, and of greater length than is usually to be met with in owls; it is barred with five dark brown bands, and a similar number of yellow ochre; several of these last are dotted in the centre with specks of dark brown, and all are tipped with white; the quills are also barred with deep brown and yellow ochre; the breast and belly are yellowish in the ground, and streaked with dark brown; the legs, thighs, and vent, are dull yellow; the three primary quills are tipped with black; the legs are feathered down to the claws, which are exceedingly sharp, black, and curved to about a quarter of a circle. The female is larger than the male, and has more white on the fore part of the body, and the markings on the upper plumage not so rich.

THE SCOPE-TUFTED OWL (*S. scops*). This is the smallest of all the tufted owls which ever appear in any part of Britain; and its visits are so few and far between, that it can hardly be regarded as a British bird. It belongs to the eastern migration, and is a very beautifully-marked creature. South and middle

Europe and Africa are the principal places of its residence, and perhaps it is more abundant in the south of Austria than in any other country. Its length is only about seven inches, but it is a well-winged little bird, and very active and daring. Its southern locality is shown by the fact of the tarsi and toes being almost entirely bare of feathers, so that the tendons would get numbened, and the bird would be unable to find its food, were it exposed to a severe climate.

The upper part of it is fine reddish ash, clouded with waving spots of black and brown, streaked with longitudinal lines of black, and very delicately crossed by very fine touches of the same colour; the under parts are of the same colours, but clearer in the tint, and the part of the legs which is feathered is reddish; the tuft consists of eight little feathers, which stand up, forming a sort of coronet; the bill is black, and the irides yellow.

The number of tufted owls in the warmer parts of the world is very great. They occur in every part of Africa, excepting the deserts. There are also many in India, in the Oriental Isles, and in Australia. America, and the American islands, are amply supplied with tropical owls, many of which have produced feathers on the head. These are in general feebler birds than the owls of the north, and their history is at the same time very imperfect. Some inhabit the woods, and others the bushy wastes; those which have the latter locality usually constructing their nests in the bushes, or in holes of the earth. Of those which frequent the open plains, and lodge in burrows, it is probable that many occupy the nests and holes of some of the smaller burrowing mammalia, and even dig into the ground to eat them. The dry plains of South America, and indeed of most tropical countries, are so completely honey-combed by the labours of small ground animals, that an owl can be at little loss for a hole to creep into anywhere.

To enter into a formal enumeration of all the named species of those owls of which notice is made in the descriptive catalogues would be a tedious task, as well as an unsatisfactory one. We shall therefore mention only one or two as specimens.

THE AFRICAN TUFTED OWL (*S. Africana*) is a native of the country of the Cape. It is about fourteen inches and a half in length. The upper parts are mottled with brown and black; the forehead and summit of the head are brown, with a small white spot on the tip of each feather, and the tufts have brown on their outer margins; the face is greyish, surrounded with a white circle and then a black one; the disc round the eye is deep yellow, radiated with blackish, and bordered with white; the under parts are brown, with cross bars and spots of white; there are some white spots on the turn of the wing; the feathers on the legs have zig-zags of black; the bill is blackish, and the irides orange. Another African species, occurring farther to the north, is the *White-cheeked Owl* (*S. leucotis*). It is found in central Africa, and is smaller than the former, being only nine inches in length. It is yellowish grey on the upper part, with the shafts and fine lines across the feathers black; the upper part of the head is yellow, streaked with dark brown; the tufts are marked in the same manner; the discs around the eyes are white, surrounded with black; the under part is coloured somewhat like the upper, only the

belly is whitish; the bill is yellow, and nearly concealed by white hairs, which are directed to the front. Besides these, there are many other African species, of which nothing can be said farther than that they are of certain sizes, shapes, and colours.

Of the owls of South America, which are very numerous, one of the most striking is the *Black-caped Owl* (*S. atricapilla*). It is a native of Brazil, between nine and ten inches in length; and the most remarkable character of the plumage is the black cap which marks the top of the head, and the tufts. The upper parts are mottled with yellow, brown, and black; the nape is white, with zig-zag lines of black; there is a half-collar of russet, varied with black; the feathers of the face are greyish, with black mottlings; and there are some white spots in the wings; the irides, the beak, and the feet, are yellow.

Of the Asiatic owls with tufts on the head we shall mention only one species, the *Oriental Owl* (*S. Orientalis*), which is a native of Sumatra, and probably of the rest of the Sundee Isles. It is rather a large species, being nineteen or twenty inches in length. The upper parts are blackish brown, crossed with zig-zag streaks of red. The tufts go off behind the outer angles of the eyes, extend outwards, and then turn upwards at the tips. They are composed of long black feathers, surmounted at the middle by shorter ones, which are streaked with brown. The face whitish, rayed with black. The under parts white in the ground colour and cross-barred with brown. The breast and flanks russet, the bill and claws whitish yellow, and the toes yellow. There are still two owls which claim the attention of students of British birds more strongly than any which have been yet mentioned. With us these are both very numerous; and they address themselves to our familiar observations, each in its peculiar way,—the one by the sound of its voice, and the other by its near residence to the abodes of man, its familiarity, and the great service it renders agriculturists by destroying mice in stack-yards and barns. The one of these is the tawny or brown owl, the other the barn or white owl.

THE TAWNY OWL. (*S. stridula*). In many parts of Europe, and in Britain especially, this is the owl, by way of eminence, which makes the nocturnal forests so dismal with its loud and lamenting cry. In aspect it is one of the most sage-looking of all the owls; and in addition to many other names, the screech-owl, among the rest, it is called "Peter," in some parts of the country; though after what Peter it is named we pretend not to say. Its head is very large, even in the solid part, and the feathers are immensely produced, especially those on the head. The legs are also of large size. The bird stands up with the line of the body nearly perpendicular; and as the body is very lanky and the legs stout, it nearly bears some resemblance to a person of small stature, with goodly spectacles across an aquiline nose, furnished with a surprising complement of wig, and altogether as demure as a judge.

The character of the tawny owl may be briefly stated as follows: its length is fifteen inches, and its weight is about nineteen ounces. The bill is light brown, the irides dusky; the feathers round the bill are white and narrow; but those between the bill and the eyes have black shafts. The general plumage of the bird is deep tawny. This colour is darkest on the head, brightest on the breast; and in some parts it is spotted with black. The belly is tawny, the feathers

of which have white margins, and a black streak down their shafts. The exterior webs of the outer scapulars are white, and some of the exterior larger coverts of the secondary quills are dotted with a white spot on their outer webs; and these form two obscure markings of white. The quills are crossed with light, tawny brown, and dusky bars; and the light colour gradually changes to white at the base. The two middle feathers of the tail, and the rump, are plain tawny; and the others are alternately barred more or less with tawny and dusky. The legs are thickly covered with feathers, or rather down, of a grey colour, speckled with brown. The claws are dusky. This is the description of the female; but it may also serve for the male; for the plumage of both sexes is exactly alike, except that the female is generally less tawny. From this latter circumstance they have been described by some as different species; but this has long since been proved to be a mistake. The only distinction between the sex that is worthy of being noticed is their difference in size. In this particular the male is considerably the smaller; his length does not exceed thirteen inches, and he seldom weighs more than from fourteen to fifteen ounces.

This species is very common not only in England but in all parts of Europe, and it is said to be met with in Newfoundland and in some parts of South America, though not in the north of that continent. In every country it is an inhabitant of the woods, and rarely makes its appearance far over the open grounds. It is understood to be an exceedingly hardy bird. In confinement it never drinks, though it eats plentifully. But no positive conclusion can be drawn from this, as to what may be its conduct in a state of nature. Its soft feathers have but little water-proof quality; and hence a rainy day reduces it to about half the bulk which it appears to have when dry. On such occasions it looks very woe-begone; and yet the rain seems to have no great effect upon its health, and a very temporary one on its plumage; for if it gets soon wet it gets as soon dry again. In strong sun-light its eyes are the weakest part of it; and yet they appear to be annoyed rather than injured, for it can look at the sun, though it cannot find its prey, or even its way on the wing, while the sun shines strongly. Sometimes, however, it remains dozing in the sun; but if it is attacked on such occasions it is very easily killed or captured. The greater part of the authorities are of opinion that it is the only British owl which hoots; and while it does this it distends the throat to the size of a pullet's egg. Its screeching cry is even more disagreeable than its hooting; and this cry, associated with the gloomy places in which the bird is usually found, and the times at which it is heard, has made it be very generally considered as a bird of evil omen. It is very rapacious in its feeding, and while it prowls about the hedges, and over the fields and covers near woods, it destroys great numbers of young game. Mice, however, are its most general food; and these it is said to skin with considerable dexterity. In the case of the larger prey, at least, it tears in pieces before it begins to eat; and both its bill and its claws are well adapted for the purpose. When pressed by hunger, which is not, however, often the case, as it keeps on rich places, it sometimes comes out voluntarily, if there is a cloud over the sun, and alights on the ground, hopping about there in search of young birds; but it never ventures far from trees, and when it is alarmed it seeks its safety in these.

The nest is usually made in the hollows of trees, in the ivy upon ruins, or in close bushes; but sometimes also it hatches its brood in a barn or granary. When it does this, the owner is very careful not to have it disturbed, in consequence of the vast number of mice which it captures for itself and its young. It continues to feed there for a long time; and if they are taken and confined in the open air, so that the old birds can visit them, they are sure to do so every night, and to bring a plentiful supply of food along with them. It is also very bold and furious in the defence of them. It should seem that, notwithstanding the largeness of its eyes, and the peculiar way in which they are adapted for nocturnal vision, it gets the first notice of its prey by the ear; for, when there are owls in the neighbourhood, if the squeaking of a mouse is tolerably well imitated, the owl will soon make its appearance, and come so near as to be easily shot. The shooting of it is a matter of wantonness, however; for its dead body is not of the smallest use, neither is it very ornamental, though it is sometimes displayed on the walls of rustic buildings.

In whatever situation it rears its brood, it never takes the trouble of making any formal nest, and indeed it has but little time for such a purpose; because the finding of its own food, and of the vast quantity which the young require, compels it to be one of the hardest-working of birds. As is the case with several of the other owls, this one not unfrequently appropriates to itself the nest of some other bird, such, for instance, as that of a rook or a jay; but it is not understood to eject the original builder, but simply to take possession after her purpose has been served. They build rather late, and are understood to do so because they thin the broods of various other birds in making adequate provision for their own. The pigeons are the birds which are understood to suffer the most in this way; and therefore the owl is destroyed with considerable assiduity whenever it makes its appearance in the presence of pigeon-houses. When the young first make their appearance, they are covered with light coloured down, and are very ragged and ill-looking creatures; but, as they advance in age, they improve. When first taken from the nest they are exceedingly shy, but their appetite soon subdues them; and if they are fed from the hand, they are not long in knowing their feeder, and come for their allowance with expressions of apparent gratitude. Even the old birds may be tamed to a certain extent, and may be retained in a captive state by removing the pinion of one wing, which of course throws them off their balance, and renders them incapable of escaping by flight. Even then, however, they are apt to hide themselves in holes, and not come abroad till the evening, at which time the sounds which they utter are exceedingly disagreeable, and altogether they are both unseemly and filthy birds.

In some respects too they must be considered as birds associated with ruin, though not with desolation. Places which are rank and foul suit them better than such as are kept with neatness, because they afford the largest supply of those animals upon which they chiefly subsist. "The screech-owl shall dwell there," is one of the pathetic and characteristic predictions of ruin to places which at one time were fair to look upon, and full of improvements, in a state of vigorous health and active enjoyment. But still, dismal as is the voice of this owl, and much as it is associated with

darkness and gloom, and that exuberance of vegetation which mantles up deserted places in fertile places, there is no doubt that, from their numbers and there wide distribution, they perform a very important part in the economy of wild nature.

THE BARN OWL, OR WHITE OWL (*S. flammea*). This owl is as much a favourite as the preceding is an object of aversion. It is, if not the most common, at least the most familiar of all the British species; and it is very generally distributed, though some of the foreign ones differ a little from that with which the inhabitants of the country are so familiar in our islands. It also occurs on the American continent, though its appearance there is perhaps a little different from what it is in Europe, and its manners are not so well known. It has frequently been confounded with the brown or woodland owl, under the general names of screech-owl, howlet, and various other names. The following are the characters of it: the male bird is about fourteen inches long, and three feet six inches in the stretch of the wings; the bill is of a whitish horn-colour, and considerably longer than is usual among its tribe. The space encircling the eyes is remarkably concave, and the radiating feathers meet in an elevated projecting ridge, bending from the bill upwards. Situated between these there is a thick tuft of bright tawny coloured feathers, which are hardly visible, except the ridges are separated. The face is white, encompassed by a narrow margin of velvety feathers, very thickset, and of a reddish cream-colour at their extremities, pure silvery white on their under parts, and shafted with black; the upper parts of the body are of a bright tawny yellow colour, richly adorned with whitish and pale purple dots, and beautifully spotted here and there with larger drops of white; the feathers of the back and wing coverts terminate in oblong spots of white, which are margined at the tip with black; the head is large and inflated; the sides of the neck are pale yellow ochre, sprinkled with small tints of dusky, and the first and second quills are of the same colours, thinly barred, and profusely sprinkled with dull purplish brown touches; the tail is two inches shorter than the tips of the wings; it is very slightly forked, of a pale yellowish colour, barred with five bars of brown, and thickly spotted with the same colour; the entire under parts are pure white, interspersed with little round spots of black; the thighs are similarly coloured, and the legs, which are long, are thinly clothed with short white down, which extends almost to the feet, which are dull white and profusely tuberculated; the toes are thinly covered with white hairs; the legs and feet are of large dimensions, and uncommonly clumsy; the turn or shoulder of the wing is tinged with bright orange brown. The old bird is whiter than the young one; some are without the spots of black on the breast, and the under colour is pale yellow; and in others a pure white.

We shall afterwards notice some of the particulars which are supposed to constitute specific differences between the European owl, and the owls, similar in manners and not much different in any respect, which are found in India, in Australia, and in some other remote countries. But it does not appear that there are any differences in the habits of the birds which are worthy of attention. In some of those remote countries they are mostly found in wild situations; but this may arise more from the nature of the country than from that of the birds. In Southern Africa,

for instance, they are said to nestle in the rocks, and to form a sort of nest of twigs and leaves, in which they deposit eggs to the number of seven or eight. In Europe, however, they are most abundant in the neighbourhood of human dwellings; their nests are in holes of walls and trees, or under the eaves of buildings; and they are contented with the natural shelter of such places, without being at the trouble of constructing any formal nest. In Europe too their eggs are far less numerous, being from two to four, and very rarely the latter number. The young remain a long time in the nesting place, and during that time the old ones are most assiduous in supplying them with food. They issue out alternately on the hunt, beat over the fields with the regularity and vigilance of spaniels; and when they see a mouse stirring, or any other prey suited to their purpose, they instantly drop down upon it, and as instantly secure it.

It is highly probable that no animal whatever regularly approaches the habitations of man, and remains there, without being of some singularly essential service to him. There is little doubt that this is the case with the barn owl, and there is as little doubt that if the encouragement of the bird were in proportion to its merits, it might be rendered a highly ornamental as well as a useful bird. Much light has been thrown upon this subject by Mr. Waterton of Walton Hall, a gentleman of some eccentricity, but possessed of most commendable zeal in the discovery of natural objects, and most delightful and glowing eloquence in the description of them. Mr. Waterton is well known for one of the most graphic and glowing books that was ever produced by a human pen, namely, his "Wanderings in the Wilds of Guiana," in which he encountered hardships, and met with adventures beyond the ken of ordinary mortals; and which, were it not for his known acuteness and veracity, might fairly be set down as the fictions of a traveller. There can be no doubt, however, that Mr. Waterton rode triumphantly from the flood of Essequibo, upon the back of a cayman, in presence of admiring men of all colours, who had contrived to draw out this American leviathan with a hook; and there can be as little question that the same delightful enthusiast in the wonders of nature out-Herculised Hercules, in grappling with the full-grown coulacanara in its den, lodging the fanged monster in his wallet, and causing it to "bleed like an ox," on the following day. These matters are beyond all scepticism; and it will readily be admitted that one who could ride the cayman and take the coulacanara captive might do what he listed with any owl that ever winged the air.

About the year 1814, Mr. Waterton resolved to establish a colony of owls, among the ivy which adorns the ancient gateway of his delightful mansion. The old house-keeper was up in arms at the prospect of such neighbours, whom she considered as of unearthly aspect and voice; but the wrath of an old woman is nothing to a man who has rode a cayman and caught a coulacanara; and, therefore, the adventurous Lord of the Manor of Walton willed that the barn owls should have a *locus standi* in the ancient gateway; *sic voluit, sic fecit*—the colony of the owls was instantly established. Nor did they fail in gratitude to so gifted and so considerate a patron. They increased and multiplied as if Walton Hall had been the very Goshen of barn owls. Their progeny speedily filled the ivy, and extended into the trees in the vicinity. They felt

quite at home, secure under so kind a protector, and probably demeaned themselves with more gratitude of heart than if they had been mewed up in cages, and fed upon the stale offal of beeves, instead of the recent and racy carcases of well-fed mice. They were, in short, very speedily on terms of the greatest familiarity, and received visitors both at their nesting places and their perches without the least apprehension. In consequence of this feeling of security, they allowed their habits, both out-door and domestic, to be studied with an ease and certainty which could not have been exercised under any other circumstances. In consequence of this, it was ascertained that, as is the case with the Peters, they repose with the axis of the body nearly in a vertical position. Neither are they sparing with their music, which, though a little discordant to some ears, is doubtless the best they can afford. They utter their strident cry morning and evening, and at some seasons the live-long night, despite the varying phases of the moon, which cannot, of course, be presumed to have much influence upon such sapient birds. During the course of eight years which, though short of twice a tithe of the beleaguering of Ilium ere it yielded to the Greeks of its time, they had not once hooted; and on this part of the subject Mr. Waterton is at issue with that great Boreal Theban in birds and beasts, Sir William Jardine, of Jardine Hall, who maintains that barn owls do hoot; but as, by his own confession, he shot them in the fact, nobody could, of course, bring the individuals to the *experimentum crucis*. Mr. Waterton's owls, however, did not submit to indignity in that passive manner which is evinced by some owls in human shape; for, upon any insult being offered to them, they hissed like serpents, and snapped like rat-traps. They also were in the habit of uttering a snoring sound; but the cause of this snoring was the very antipodes of that which lulls to sleep, being the complaint of the young when hunger wrung their stomachs, and every body knows that hunger is the least sleepy affection, both of man and beast. The researches of Mr. Waterton into the natural history of this domesticated colony of owls are of great value; and they are not of greater value in any other respect than inasmuch to show that snoring, on the part of a barn owl, is anything but a concomitant of sleep. It is only done under the sleepless feeling on the part of the young to which we have alluded; and, therefore, any one who wishes to have an owl for a bed-fellow, has nothing more to do than give it due infarction for supper, and it will sleep as sound as a top, until the craving of its maw sets it snoring in the morning.

In endeavouring to prevent any deficiency of their numbers, those owls are labouring for the production of more owls early and late; and in the general locality to which we have alluded, they drudge at their family duties in the fogs as late as the month of December. This philo-progenitation, though it may not tally exactly with the dogmas of the phrenologists, is a sort of constructive proof that the owls know the economy of the world, and that the world could not be carried on without them; and Mr. Waterton's observations afford other proofs that, without the diligent fagging of their beaks and claws, mice might, perchance, shake the stability of the system of the world, as Homer, in his *Batrachomyomachia*, once alleged they did, in the case of the croakers of the fens. When the owls have their broods astirring, Mr. Waterton estimates that from four to five mice are brought

to the owl's nest every hour; and not only during the night, but absolutely during the day. The quids which they cast up, after no more digestible part of the mouse remains, average a bushel in sixteen months; and each individual pellet of the casting contains the skeletons of about half a dozen mice. If, therefore, every one were to be as zealous in the cause of owls as our delightful naturalist of Walton Hall, cats, and all the discordant din of their cat-continuing operations, might cease; though how this might affect the plague of black beetles, is well worth the consideration of the domestic naturalist. Owls, cats, and black beetles, hang so equally in the balance, that it would require a conjuror to say which of them would kick the beam. For philosophic men in such cases, however, there is always a *point d'appui*, upon which no mistake can be made—as each man is entitled to select that wisdom which is most germane to his own. There is no doubt, however, that barn owls are exceedingly useful birds in their way; and, perhaps, the best mode of arriving at a rational conclusion with regard to their utility would be, to leave the point at issue to the decision of those farmers which can best judge whether a barn owl is useful about their premises or not.

That they are useful we firmly believe; and as they are very handsome birds in the markings of their plumage, they are really ornamental. One should love them, because they do not pass away before the progress of cultivation, but rather increase in numbers as richness and cultivation in the fields increase.

There are several other owls very much resembling in their manners, and situated in every variety of temperate and tropical latitudes, to which we might, perhaps, have alluded; but the species of which we have given some notice, afford specimens of all the more striking varieties, and to them we shall, therefore, restrict our notice of “the birds of wisdom.”

OXALIDEÆ. A natural order, containing three genera, viz., *Averrhoa*, *Biophytum*, and *Oxalis*, of which there are above one hundred and twelve species. The *Oxalis*, or wood-sorrel, and its typical allies, are herbaceous, or suffruticose (rarely arborescent) plants, with alternate compound leaves, sometimes simple by abortion, and occasionally, but very seldom, opposite or nearly whorled. The inflorescence is axillary, seldom solitary, and the flowers are regular and united. The calyx consists of five persistent sepals; corolla of five deciduous petals, and spirally contorted before expansion; stamens ten, borne on awl-shaped filaments, often monadelphous at the base; the anthers are two-celled and innate; the germen is free and five-celled; the styles five and distinct, variable in length, with pencil-formed stigmas. The fruit is capsular, seeds few; when young they are enclosed in an integument or arillus, which at maturity bursts elastically, and expels the seeds.

The *Averrhoas* differ from the *Oxalideæ* by their arborescent character. *A. belimbi* is the cucumber-tree of Goa. *A. carambola* is the camrango of Hindoostan, and also bears an eatable fruit, but which are mostly used green for tarts or stews. The leaves of this tree are sensitive. The leaves of the *Biophytum* are also irritable.

OXEYE DAISY is the *Chrysanthemum leucanthemum* of Linnæus, a British weed often seen on arable land.

OXINOE. A genus of molluscs, established by

Rafinesque, but we have no certainty respecting its difference from the *Sigaretus*; it is, however, asserted by Rafinesque to be an external shell; but if the branchiæ are disposed as he asserts, the distinction is much more considerable: not having the animal before us, we cannot venture to pronounce a judgment.

OXLIP is the *Primula elatior* of Jacquin, a common British plant found on the borders of fields.

OXYBAPHUS (Ruiz and Pavon). A genus of herbs, chiefly creepers, natives of South America, belonging to *Nyctagineæ*. These plants thrive during our summer in the open air, but require to be taken up in winter and replanted in the spring.

OXYCOCCUS (Linnæus). This a British bog plant, and the *O. palustris*, or cranberry, of botanists. The flowers are octandrious, and the plant is now arranged as one of the *Ericaceæ*. There are several closely-allied bog or moor plants indigenous to northern latitudes. *Vaccinium myrtillus* is the bilberry; *V. uliginosum*, the bleeberry; *V. vitis Idæa*, the cowberry; our present plant is the cranberry. *O. macrocarpus* is the great-fruited cranberry; and various other *Vacciniums* are known as whortleberries. The fruit of all are eatable.

OXYLOBIUM (Andrews). A genus of ever-green shrubs, natives of New Holland, belonging to *Leguminosæ*. They thrive in loam and moor-earth, and are increased by cuttings or seeds.

OXYPORUS (Fabricius). A genus of rove-beetles (*Brachelytra*), having the maxillary palpi filiform, and the labial terminated by a large crescent-shaped joint; the body is short and thick; the antennæ thick, perfoliated, and compressed. The species are handsomely coloured, and of considerable rarity; they frequent decaying agarics, boleti, &c. The type is the *Staphylinus rufus*, Linnæus.

OXYSTOMA. Is the fifth family of the second order *Asiphonobranchiata*; second class *Paracephalophora*, and the varieties or species of the genus *Janthina* constitute it. These shells are described in their alphabetical arrangement.

OXYTELUS (Gravenhorst). A genus of rove-beetles (*Brachelytra*), and the type of the subfamily *Oxytelides* (see *BRACHELYTRA*). The species are very numerous, of a black colour, and frequent dung and fungi.

OXYTROPIS (De Candolle). A numerous genus of European herbaceous perennials, bearing papilionaceous flowers, and belonging to *Leguminosæ*. Some of the species are admitted into the flower-garden for the beauty of their flowers, and where they are easily increased by division or seeds.

OYSTER (*OSTREA EDULIS*, Linnæus and modern authors—Common Oyster). Oysters inhabit the European and other seas in countless masses; they are generally so well known as nutritious and palatable delicacies, that no description of them is necessary in that respect. Medical writers appear to differ respecting their medicinal virtue, but the greater number agree as to their being wholesome, and generally adapted to most constitutions.

Most of the coasts of England produce oysters in great abundance; but the coasts of Essex and Suffolk are chiefly celebrated for their excellence. The oyster fishery is regulated by a particular court, and a long course of custom has established some very curious laws in this branch of commerce. In the month of May the fishing commences by sepa-

rating what is termed the spawn from the cultch, the former being returned to the beds to preserve the stock for future seasons. After this month it is felony to carry away the cultch; and it is besides punishable to take any oyster between whose shells a shilling will rattle when the valves are closed. The reason of heavy penalties being inflicted on the destruction of the cultch appears to be, that when this is removed, the ouse increases, and muscles and cockles breeding in the beds destroy the oysters by occupying the places where the spawn should be cast. There is also some penalty for not destroying the *Asteria* (star-fish) found in the neighbourhood of oyster-beds, as they are very destructive to these fish by inserting their rays as the shells lie open, and devouring the animals within, a circumstance noticed by the accurate and ancient naturalist Oppian, in the following lines:—

The prickly star creeps on with fell deceit,
To force the Oyster from his close retreat.
When gaping lids their widen'd void display
The watchful star thrusts in a pointed ray,
Of all its treasures spoils the rifted case,
And empty shells the sandy hillocks grace.

The principal breeding time of oysters is in April and May, when they cast their spawn, or *spats* (as it is called by the fishermen), upon rocks, stones, shells, or any other hard substance that happens to be near the place where they lie, to which the *spats* immediately adhere till they obtain their firm or testaceous crust, resembling drops of greenish tallow, and the substances, of whatever nature they may be to which they adhere, are called *cultch*. From the spawning time till about the end of July, the oysters are said to be sick, but by the end of August they become perfectly recovered. During these months they are considered out of season, and bad eating. This is known on inspection by the male having a black and the female a milky substance in the gill. Oysters are commonly considered in season after that time till the ensuing year, in the months with an *r*, beginning with September.

Oysters are not reckoned in high condition for the table till they are about a year and a half old, so that the brood of one spring are not taken for the market, till at least the September twelvemonths afterwards. When younger than these happen to be dredged, they are always again thrown into the sea. The fishermen ascertain the age of oysters by the broader distances or interstices among the rounds or rings of the convex shell, which in all bivalves indicate the annual increase.

Oysters are taken from their native beds by dredges, formed of a net held open by means of an iron scraper, drawn over the beds by a rope attached to a boat. As soon as they are thus removed from their beds, they are stored in pits formed for the purpose, furnished with sluices, through which, at the spring tides, the water is suffered to flow. This water, being stagnant, soon becomes green in warm weather, and in a few days afterwards the oysters acquire the same tinge, which renders them of great value in the market; but they do not acquire their full quality, and become fit for sale, till the end of six or eight weeks.

The oysters in the pits are of course always lying loose; but on their native beds they are in general fixed, from the time they are cast, by their under shell; and their quality is said to be materially

affected by their being laid in the pits, with the flat shell downwards, not being, as it is supposed, able, in that position, to retain sufficient water in the shell for the animal's support.

With regard to the locomotive powers of the oyster, upon which much speculation has been exercised, every one at all acquainted with the structure of the animal must have observed that this cannot take place, as is usual with many other bivalves, by means of the foot, for such an appendage is altogether wanting in the oyster.

The Abbé Dicuemaire, who was a close and accurate observer of the habits and manners of these, as well as other marine animals, assures us that oysters possess the faculty of moving themselves, which is effected by the singular effort of ejecting water with considerable force from their shells, enabling them thus to start to a limited distance backward, or laterally, on one side. He says that any one may amuse himself with the squirting and motions of oysters, by putting them in a plate placed in a horizontal position, which contains as much seawater as is but just sufficient to cover them.

The oyster has been considered destitute of motion, and every species of sensation, by most authors; but the above-mentioned naturalist states that it is competent to perform movements, consonant to its habits, either of comfort or defence; and instead of being destitute of sensation, it is even capable of deriving knowledge, or instinctive reason, from experience.

When removed from situations constantly covered by the sea, from want of experience they open their shells, lose the nourishment of the water contained in them, and in a few days die. But, when taken from similar situations, and laid down in places from which the sea occasionally retires, they feel the effect of the sun's rays, or of the cold air, or perhaps, apprehending the attack of an enemy, they learn to keep their shells closed till the tide returns.

Oysters breathe by means of branchiæ or gills. They draw the water in at their mouth, which is a small opening in the upper part of the body, drive it down a long canal that constitutes the base of the gills, and so out again, retaining the air for the necessary functions of the body. Thus their ejecting the water seems to serve the double purpose of aiding the motion of such as are free, and of supplying the animals with air. These observations are principally derived from the Abbé Dicuemaire, in *Philosophical Transactions*; Haak on the *Breeding of Colchester Oysters*; and Tuke on the *Generation and Ordering of Oysters*, in *Spratt's History of the Royal Society*.

As an article of luxury, oysters were known at a very early period of time. The civilised Athenians held them in great esteem as a dainty food. They were not common at Rome, and consequently brought very high prices; yet Macrobius assures us that the Roman pontiffs never missed having them every day on their table. Apicius, the third of that name, was excessively fond of oysters, and used to pay for them a most enormous price. Those of the Lucrine Lake, and Abydos in the Hellespont, being esteemed by far the best, were sent as delicate presents to men of high rank. The Emperor Trajan, when carrying on war against the Parthians, received from this Apicius several baskets or barrels of them; and Pliny has not thought it beneath the dignity of an historian to record the names of such persons as

were celebrated for their parks or preserves of oysters.

✓ The edible oyster of Britain was deemed superior to that of all other countries, and was famed from the time of Juvenal, who flourished at the beginning of the second century. In satirising the epicure Montanus, he writes :—

“ He, whether Circe's rock his oysters bore,
Or Lucrine Lake, or distant Richboro's shore,
Knew at first taste.”

Sergius Orata appears to have been the first inventor of the stews, or layers of oysters, similar to those of our present time. He derived great profit from them, as an article of commerce, to pamper the luxurious taste of others, rather than to gratify his own appetite. Orata gained much credit for his Lucrine oysters, for, says Pliny, the British were then not known.

Leeuwenhoeck, whose microscopic investigations have led to so many interesting discoveries in natural history, gives the following observations respecting the oyster :—“ In the clear liquor around the animal, many minute round living animalculæ have been found, whose bodies being conjoined, form spherical figures with tails, not changing their place otherwise than by sinking to the bottom ; being heavier than the fluid, these have been seen separating, and coming together again. In other oysters animalculæ of the same kind were found not conjoined, but swimming by one another, where they seemed in a more perfect state, and were judged by him to be the animalculæ or semen of the oyster.

“ A female oyster being opened, incredible numbers of small oysters were seen covered with little shells, perfectly transparent, and swimming along slowly in the liquor ; and in another female the young ones were found of a brown colour, and without any appearance of life or motion.”

✗ In the month of August oysters are supposed to breed, because young ones are then found in them. Leeuwenhoeck, on the 4th August, opened an oyster, and took out of it a prodigious number of minute oysters, all alive, and swimming about nimbly in the liquid, by means of certain exceedingly small organs, extending a little way beyond their shells, and these he calls their beards.

In these little oysters he could discover the joinings of the shells, and perceived that there were some dead ones, with their shells gaping. These, though so extremely minute, “ were seen to be as like the large oyster as one egg is to another.”

As to their size, he computes that 120 of them in a row would extend an inch, and consequently that a globular body, whose diameter is an inch, would, if they were also round, be equal to 1,728,000 of them. He reckons 3,000 or 4,000 are in one oyster, and found many of the embryo oysters among the beards, some fastened thereto by slender filaments, and others lying loose. He likewise found animalculæ in the liquor, 500 times less than the embryo oyster.

A very curious fact rests upon the evidence of M. de Lavoge, who recently remarked, on opening an oyster, a shining matter or bluish light, resembling a star, about the centre of the shell, which appeared to proceed from a small quantity of real phosphorus. On being taken from the animal, it extended to nearly half an inch in length, and, when immersed in water, seemed in every respect the same as the phosphorus

obtained from bones ; but, as the oyster was perfectly alive and fresh, the light could not proceed from any decomposition of the shell of the animal. How and to what purpose was it then produced ? Future observation may possibly throw a fresh light on this luminous property.

The space allotted to us will not permit our enlarging much more on the history of the oyster. We must necessarily, however, add a few more observations respecting this delicacy and very-important branch of British commerce. We have before us a well authenticated account of the quantities annually sold at Billingsgate alone, and it exceeds all reasonable imagination. The beds occupy portions of the sea, in shallow parts, extending for miles square ; and, in some places, the depth of stratum is very considerable. Various companies are formed who send the produce of the season to market ; and each has a particular name to indicate the quality. The price varies considerably, but the quality but little, when the oysters are prepared for sale by subsequent attention, or after-feeding, as it is termed. Many persons have different modes of fattening oysters ; but none is positively asserted to be the best. Well-salted spring-water frequently changed agrees better with the fish for the short time occupied before its consumption, than any admixture of oat-meal or other farinaceous matter, frequently added by the London retail fishmongers. The sale of oysters at Billingsgate is regulated by the city laws, and an inspector appointed to each boat, as its cargo is sold off. A very trifling due is claimed by the city, but it averages a large income in the aggregate ; and the trade produces some of the best sailors in the world : the risks they incur would daunt any other race of men than the British tars, whose courage and perseverance in the eminent risks their dangerous profession exposes them to, has rendered our sea-girt isle the admiration and envy of every other nation. A sailor may be said to be an animal *sui generis* in the scale of creation ; but to his prowess we owe our greatness principally, as one of the greatest and most enlightened nations of the world. Some idea may be formed of the extent of oyster banks or beds by the following extract from an observant and voracious person, who states, that “ of all the natural phenomena on an extensive scale, which arrested his attention during a visit to America, exciting his admiration of the ways of Providence, none equalled the oyster banks on the seaboard of Georgia. The land from the sea is completely alluvial for about the distance of twelve to eighteen miles, and in general consists of uncultivated marsh lands, through which an iron rod might be thrust to the depth of eighteen or twenty feet.

“ A great number of large creeks and rivers are found meandering through these marsh lands, and, owing to the sinuosities invariably resulting from running water, the bends of these rivers would, in a short time, cut away the adjoining land to such an extent, as would make the whole seaboard a quagmire. But it is a remarkable fact, that wherever the tide bends its force, its effects are counteracted by walls of living oysters, which grow upon each other from the beds of the rivers to the very verge of the banks. These hillocks are often found in bunches among the long grass growing upon the surface of the soil. They are in such abundance, that a vessel of a hundred tons might load herself in three times her own length. These banks are the favourite resort of fish and birds,

as well as of the racoon and some other quadrupeds, which feed upon oysters, both by night and day. Bunches of them, sufficient to fill a bushel, are found matted, as it were, together, and the neighbouring inhabitants will light a fire upon the marsh grass, roll a bunch of oysters upon it, and then eat their contents. This barrier of oysters, like rocks of coral, must offer the strongest resistance to the force of the tide." We will merely add, that the oyster affords one of the most striking instances of the wisdom and goodness of God towards man, in providing for his wants an inexhaustible store of nutritious food; proving also the constant conclusion to be drawn, that the good things allotted to man's use immensely exceed the noxious ones, and, by their abundance, seem to point out that which must be best for his consumption.

OZOTHAMUS (Dr. Brown). A genus of soft-wooded shrubs, natives of Van Diemen's Land. They bear syngenesious flowers, and of course belong to *Compositæ*. They were called *Eupatorium* by Labillardière. They succeed well under green-house management.

PACHIDENDRON (Willdenow). A genus of succulent plants, natives of the Cape of Good Hope. They are closely allied to the genus *aloe*, and were united to that genus by Mr. Haworth. Like the *aloes* they have hexandrous flowers, and belong to *Hemerocallidæ*. Their chief distinction is their arborescent part, and they thrive in lime rubbish soil, with moderate watering. They are increased by offsets.

PACHYTA (Megerle). A genus of longicorn beetles, belonging to the family *Lepturidæ*, having the body short, the elytra broad and sub-parallel, entire at the tips. These are handsome beetles, of which there are three or four inhabitants of this country, including the *Leptura collaris*, Linnæus, which is about one third of an inch in length, of a black-blue colour, with the thorax and abdomen red. They are found in flowers.

PACILOPODA, (Latreille). An order of crustaceous animals belonging to the great division of *Entomostraca*, having the legs of variable form, the anterior, of an indefinite number, being formed for walking, or prehensile, whilst the posterior are lamelliform or pinnated, and either natatory, or serving as organs of respiration (*branchiæ*). It is, however, especially by the absence of jaws and under jaws that they are distinguished from the other crustacea, these organs being either replaced by the basal part (*cora*), of the six pairs of fore-legs, which are furnished with minute teeth, or the oral apparatus, consisting in an external siphon, in form like an articulated rostrum, or in other suctorial instruments whose structure is not well determined. The body is generally covered either entirely, or for the most part, by a shield-like carapax of a single piece in the greater number, but bipartite in a few, and always exhibiting a pair of eyes when the organs of sight are present. Two of the antennæ (*cheliceræ*, Latr.) are in general cheliform, and perform the office of pincers; the number of the legs is generally six pairs, in some, however, there are only five pairs, whilst a few have eleven pairs. They are generally parasites, living upon the bodies of other aquatic animals, especially fishes.

This order comprises two principal sections or suborders:—

1. *Xyphosura*, Latreille, in which the carapax is bipartite, the suctorial apparatus wanting, and its place supplied by the dilated bases of the fore-legs. Typical genus *Limulus*, or king crabs. See *LIMULUS*.

2. *Siphonostoma*, Latreille, in which the mouth is more or less evidently suctorial, and the carapax composed of a single piece. There are two families, *Caligidæ* and *Dichelestionidæ*. (*Lernæiformes*, Latreille.)

PÆDERIA, (Linnæus.) A genus of evergreen shrubs, natives of the Mauritius and China. Their flowers are pentandrous, and their berries are transparent. They belong to *Rubiaceæ*; grow rapidly in the stove, climbing and supporting themselves on other plants, and are increased by cuttings.

PÆDERUS, (Fabricius.) A genus of small but handsome rove-beetles, *Staphylinidæ*, belonging to the sub-family or tribe *Stenides*, (see *BRACHELYTRA*), having the antennæ inserted before the eyes, filiform or gradually thickened and longer than the head, the body long and narrow, the jaws toothed internally, and terminated in a point, and the tarsal fourth joint bifid. The type is the *Staphylinus riparius*, Linnæus, about a quarter of an inch long, of a red colour, with the head and tip of the abdomen black, and the elytra blue. These insects are found upon the margins of water and in other damp situations, their motions being in general very quick.

PÆLOBIUS (Schönherr). As restricted by British entomological authors, this genus of water beetles (*Dyticidæ*) comprises but a single species, *Dyticus Hermannii*, Linnæus, which has an exposed scutellum, the legs gressorial, and the body very convex. It is nearly half an inch long, and of a reddish brown colour, with the surface of the elytra black. It is a local insect, but occurs in some abundance in some of the ponds round London.

PÆONIA (Linnæus). A very conspicuous genus of herbaceous and suffruticose plants, chiefly natives of the northern parts of the world. The flowers are polyandrous, and belong to *Ranunculaceæ*. The roots are, for the most part, thick and fleshy, and the flowers are large and of the most brilliant colours. There are five half-shrubby species, introduced from China; and a great number of herbaceous sorts, obtained from Siberia, and other parts of the northern hemisphere. The shrubby sorts are increased by cuttings or layers, and the herbaceous species and varieties by division of the roots. The pæonias were highly esteemed by the ancient Greek physicians, but their praises are too extravagant for sober repetition. Among other superstitions, they believed it to be of divine origin, an emanation from the moon, and that it shone during the night, &c. Modern times are not, however, free from some remnants of these absurdities. "The anodyne necklaces," says Burnett, "still sold to prevent convulsions in children, and to ease dentition, are made of beads turned from the root of the common pæony."

PAGURUS (Fabricius). A remarkable genus of long-tailed crustacea (*Macrura*), distinguished by the slender texture of the shell or carapax, and the fleshy structure of the abdomen, which is generally twisted on one side and bag-shaped. The two fore-legs are terminated by a didactyle claw, the four following by a simple point; but the four posterior, which are smaller than the others, are armed at the end by a small pair of didactyle claws; the basal joint

of the footstalk of the lateral antennæ is furnished with a spine or elongated point.

These crabs are of very common occurrence upon the shore, and are known under the name of the hermit-crabs, from their singular and solitary mode of life, which is passed entirely in old and forsaken univalve shells, exhibiting a most beautiful instance of that connexion which is always found to exist between the structure and functions of animals; hence it is that we see the reason why the abdomen of these crabs is of a soft and fleshy nature, since, if it were hard and shelly, like that of the lobster, it would be impossible for it to accommodate itself to its tortuous abode, whereby it is enabled to escape from those dangers, to which it would be exposed from the boisterous element in which it resides, if it were not thus amply secured from harm. The species of which this genus is composed are very numerous, and are found in all parts of the globe. The following extract from Mr. Bennett's Wanderings in New South Wales will be read with interest, as it contains a satisfactory account of the habits of these animals:

"A great number of the *Paguri*, hermit, or soldier-crabs, of different sizes, were running about the beach; two large specimens that I found had each taken possession of the *Dolium perdir*, or partridge shell, to which they were as firmly attached as if in their natural habitation. The smaller kind inhabit *Muriceæ*, *Trochi*, *Neritæ*, *Helices*, *Lymnææ*, *Cerethii*, and the univalve shells. In some instances I saw large shells of *Harpa*, &c., inhabited by very small animals of this kind, moving their heavy and cumbersome dwelling slowly and with difficulty: there were some of a red, and others of a sea-green colour, but the larger were invariably of a beautiful lilac. May not this change of colour depend upon their age? The *Paguri* feed upon dead animals, fish, and all kinds of offal, as well as vegetable matter, such as skins of plantain, remains of cocoa-nuts, fruits, &c. I have often observed a number of these creatures, of various sizes, congregated about a dead and putrid fish; and it is ludicrous, on disturbing them in the midst of their feast, to see them marching away, fumbling and overturning one another in the hurry, causing a clattering noise to proceed from this collision of their borrowed coverings, and, should they not be able to escape capture, they draw themselves closely into the shell, closing the aperture so firmly, by closing the claws over the entrance, as to render it impossible to extract them without breaking the shell to pieces. Thus secured, they remain immovable and apparently dead, and may be kicked or thrown about without giving any indications of life; but danger past, they emerge partly from the shell as before, and move briskly away. The natives use them occasionally, but rarely, as food."

The manœuvres of these creatures, when their habitations have become too small for them, are not less ludicrous. Crawling slowly along the line of empty shells, &c., left by the last wave, and unwilling to part even with their incommodious domicile until another is obtained, they carefully examine, one by one, the shells which lie in their way, slipping the tail out of the old house into the new one, and again betaking itself to the old one, if this should not suit. In this manner they proceed until they have found a habitation to their liking, which, as we learn from Mr. Bennett, is by no means proportioned to their size.

There are several British species of this genus figured by Leach in his "Malacostraca Podophthalma Britannica," the commonest and best known being the *Cancer Bernhardus* of Linnæus, (*Pagurus Streblonyx* of Leach), which is of a moderate size. Its claws are armed with short spines, and are somewhat heart-shaped, that on the right hand side being the largest. This genus constitutes the type of a family of long-tailed crabs (*Paguridæ*), which comprises the following genera—*Birgus*, *Pagurus*, *Cænobita*, and *Prophylax*. The type of the genus *Birgus* (which is generally distinguished by the harder consistence of their teguments, orbicular tail, and reversed, heart-shaped carapax,) is one of the largest crustaceous animals. It is the *Cancer latro* Linnæus, or the *Baerskrabbe* (purse crab) of Rumphius, and is an inhabitant of Amboyna, and was found in abundance by Mr. Cuming in Lord Hood's Island, in the Pacific, living at the roots of trees, and not in forsaken shells. When disturbed, it puts itself into a threatening attitude, and retreats backwards, making a noise with its claws. It has been long asserted that it climbs the cocoa-trees; and Messrs. Quoy and Gaimard, in proof of the correctness of this assertion, fed this species for many months on cocoa-nuts; Mr. Cuming also discovered that it climbs the *Pandanus odoratissimus*, a kind of palm-tree, or feeds upon the small nut which grows thereon.

PALÆMONIDÆ (SALICQUES, or CARIDES, Latreille). A very extensive family of long-tailed crustacea (*Malacostraca macrura*), of small or but moderate size, having the intermediate antennæ inserted higher than the lateral, the footstalk of the latter being entirely covered by a large scale; the body is arched, and of a slight consistence, the front being often produced over the head into a long and serrated spine; the antennæ are always porrected, the lateral pair being generally very long and slender, and the intermediate pair often terminated by two or three threads; the outer pair of foot jaws considerably elongated and slender, rather resembling palpi; the external plate of the natatory caudal apparatus is always divided into two parts; the central plate is long, narrow, and pointed; the false or abdominal prolegs consist of five pairs, and are long and generally foliaceous.

This family is well exemplified by the shrimp and prawn, as well as by other species which, in various parts of the world, are much eaten either by being simply boiled, or salted and potted. The genera are very numerous, and are distinguished by the number of filaments of the intermediate antennæ, the number of didactyle claws, the annular structure of the tibiæ of some of the legs, &c. The chief genera are *Atya*, *Crangon* (which see), *Alpheus*, *Hippolyte*, *Pandalus*, *Palæmon*, and *Athanas*. The genus *Palæmon*, Fabricius (the type of which is the common prawn, *P. serratus*, Pennant), is distinguished by having three setæ to the internal antennæ, the four anterior legs didactyle, the second pair being larger than the first pair, which are folded back, the wrist articulate, and the front of the carapax very much elongated and toothed.

PALINURUS (Fabricius). The spiny lobster. See **ASTACIDÆ**.

PALIURUS (Tournefort). A genus of deciduous shrubs, natives of the south of Europe and Nepal, belonging to the order *Rhamnææ*. The Christ's thorn (*P. aculeatus*) is a prickly shrub, but its flowers are ornamental. They succeed well in any garden soil, and are increased by layers or cutting of the roots.

PALLADIUM. We are indebted to the late Dr. Wollaston for the first accurate account of this mineral. That distinguished philosopher found it associated with platina and iridium. It is of a white colour, and nearly resembles platina in its external appearance. Palladium is mostly found in the gold districts of South America, but its scarcity and consequent high price forbid its extensive use in the arts.

PALMA CHRISTI is the *Ricinus communis*, or castor-oil plant of Linnæus. A well-known flower-garden annual.

PALMÆ. A natural order of magnificent and remarkable plants containing forty genera, and one hundred and thirty species already discovered and described, though it is well known that many more exist in the yet unexplored wilds of South America and other tropical countries.

"Palms," says Dr. Von Martius, "the noble offspring of Terra and Phœbus, are natives of those countries, where the rays of the latter are daily beaming. In all such climates they are to be found, with this limitation, however, that in the southern hemisphere they do not overstep the thirty-fifth degree of latitude, nor in the northern the fortieth. Most species are found fixed and confined within narrow bounds; for it comes to pass, that wherever a district is characterised by striking peculiarities of soil or climate those species exist which are not found elsewhere; but few extend over a large extent of surface, as the *Cocos nucifera*, *Acrocomia sclerocarpa*, *Borassus flabelliformis*, &c. It is probable that the number of palms existing on the face of the earth will be found by future travellers to amount to as many as a thousand species. Most of them love the margins of springs and streams, but few establish themselves on the shores of the ocean, and a yet smaller number ascend into the alpine regions of their country; some collect in large forests; some are scattered singly or in groups in woods or on plains. Palms have followed the footsteps of man, to whom their fruit yielded food, drink, and oil; their stems—houses, arms, utensils, flour, and wine; and their leaves—cordage, and roofs for habitations. In cultivation, their soil should be slightly saline: they are only propagated by seeds."

The palms are arborescent monocotyledons, with generally simple cylindrical lofty stems, occasionally, but very rarely, branched. The pinnati-sect leaves are large, petiolated, and crowded at the extremities of the trunk; the leaf-stalks partly embrace the stem, are invested with stipulaceous reticules, and cover the stem, when they fall, with successive scars. The structure of the stem is decidedly endogenous. The inflorescence as in catkins, or racemes, furnished with bracteolæ, and often enveloped in a large spathe. The perianth is small and of six pieces, disposed in two series equivalent to calyx and corolla; the stamens are rarely three in number, most frequently six; the styles are three; stigmata simple; germen superior, three-celled, two or one often abortive, and the cells are one-seeded; the fruit is either a berry or a drupe.

The cocos, or cocoa-nut bearing, is one of the most useful of the palms, as affording a wholesome kernel, milk, and cream. The sap is a wholesome beverage, and which, when fermented, yields an ardent spirit. The *Phoenix dactylifera* is also a most valuable fruit-tree, and indispensable to the natives of the countries where it is naturally found or cultivated. The

other genera are mentioned under their respective names.

PALPUS (in the plural, **PALPI**). The articulated organ attached at the back or side of the lower jaw of many insects. See **INSECT**.

PANAGÆUS (Latreille). A handsome genus of coleopterous insects belonging to the family *Carabidae*, and sub-family *Harpalides*, having the two basal joints of the tarsi of the males alone dilated, the head very small compared with the rest of the body; the eyes large and globose; the jaws very small, and the thorax suborbicular. They are mostly of black colours, ornamented with red or yellow spots, the type being the *Carabus crux major*, Linnæus, so named from the elytra exhibiting a black cross. It is found abundantly in the fens in Huntingdonshire. There is another British species, *Pan. quadripustulatus*. Some of the exotic species are of large size.

PANDANEÆ. A small natural order containing only two genera and twenty-one species. They are very remarkable plants, with the habit of the pineapple, but much more robust and tree-like. From the position of the leaves developed in spiral order, they are called the screw-pine. The stem rises to a considerable height, bearing a thick tuft of rigid foliage presenting the habit of palms. New births of roots are gradually produced from the joints of the stem, higher and higher up every year, which in time fix themselves in the ground; the first or oldest roots in the mean time dying away, so that at last the head of the plant is supported by the younger roots arranged like a series of buttresses all round. *Pandanus odoratissimus*, as well as the other species of the genus, says Burnett, exhibit a *strange semblance of instinct*, in the development of aerial roots at different distances on their stems, by which their life is prolonged, and the fate common to most of the arborescent endogens for a time avoided. It is very curious to observe the *device of nature* to strengthen the stem, and to prolong the existence of these handsome plants. Being endogenous (*endon*, inside; *genomai*, to grow), all growth proceeding from within, the older and harder formations are outermost. But the diameter of the first-formed stem, being comparatively small, could not bear the weight of the head afterwards formed, were it not for the propping roots which descend from the more elevated part of the stem. This is the *pandang* of the Malays, and is found in all the warm countries inhabited by these people. The stamiferous flowers are delightfully fragrant, and are said to yield one of the richest perfumes known. The soft bases of the leaves and the pulpy part of the fruit, although unpleasant, are eatable, and the Asiatics feed on them in times of scarcity; at other times they give them to their cattle as fodder. The soft spongy roots are made into corks; the fibrous leaves and stem are made into mats and baskets by the Tahitians, who stain them of different colours; they are also used for thatching and for cordage, and made into a coarse kind of sacking for exportation of dry goods, as coffee and the like. The *Faquahine*, which Mungo Park found in the interior of Africa, the fruit of which, he says, when ripe, explodes and inflames spontaneously, by which many serious accidents have occurred, has been ascertained by M. Beaufort to be a species of *Pandanus*, and he confirms Park's description.

The species grow well in our stoves, potted in

B B

light loam, but have never been brought to flower under such treatment.

PANIC GRASS is the *Panicum colonum* of Linnaeus, which, with many other species, form one of the largest genera belonging to the order *Gramineæ*. The species are mostly natives of tropical countries. The *Panicum miliaceum* is the millet, an agricultural plant, the grain of which is both dietetic and medicinal. Millet is also much used for feeding poultry.

PANORPIDÆ (Leach). A family of neuropterous insects, belonging to the section *Filicornes*, and having five joints in all the tarsi, and the front of the head produced into a long and narrow beak. The species are comprised in the Linnaean genus *Panorpa*, in which the antennæ are setaceous and inserted between the eyes; the body long, the head vertical, and the prothorax very small. There is very considerable diversity in the appearance of the sexes of some of these flies. The family comprises the genera *Nemoptera* (which see), *Bittacus*, *Panorpa*, and *Boreus* (which see). The typical genus *Panorpa*, Linnaeus, is distinguished by having the four wings of equal size; the ocelli three in number; the abdomen of the male long and jointed, and terminated by a remarkable instrument like a pair of pincers, so that this part of the body bears considerable resemblance to the tail of the scorpion, whence these flies are termed scorpion-flies; the abdomen of the female is long and pointed at the tip; the legs are of moderate length.

The type of the genus is the *Panorpa communis*, Linnaeus, which is rather more than half an inch long, of a black colour, with the beak and tip of the abdomen red, and the wings spotted with black. It is very common, and is found in hedges and grass. There are several other nearly-allied British species.

PANURGUS (Panzer). A genus of bees, belonging to the family *Apidae*, and sub-family *Andrenoides*, Latreille, having the mandibles destitute of teeth; the terminal joints of the antennæ in the females form a sort of spindle-shaped mass of a nearly cylindrical form; the hind-legs are very hairy, and the wings have only two sub-marginal cells. There are two British species, the type being the *Apis ursina* of Linnaeus. They are of rare occurrence, and their economy is unknown.

PAPAVERACEÆ. A natural order containing twelve genera and above sixty-five species. The poppies and their typical allies are annual or perennial herbs (rarely under-shrubs), with milky juices, varying in colour from white to yellow, orange, and crimson. The roots are fibrous, stems round, with alternate simple leaves, either on footstalks or sitting, and without stipules. The flowers are solitary, regular, and on long peduncules. The calyx is of two deciduous sepals, the petals four or some multiple of that number. The stamens are eight, twelve, or sixteen, &c., commonly indefinite and collected into four groups, one near the base of each petal, and hypogynous. The filaments are filiform and free; the anthers innate and two-celled. The germen is free and symmetrical, formed of two or more united carpels, sometimes stipitate or sitting, in general one-celled. The style is short, or wanting; and the stigmas two to four, or many, radiant and persisting. The fruit is a one-celled capsule, opening by valves or pores. Seeds numerous.

The twelve or thirteen genera included in this type form a very natural group. In properties they are as accordant as in form, being universally nar-

cotic, although they differ in the degree in which the sedative principle is evolved.

The poppies are, many of them, very ornamental plants; but their chief importance results from the narcotic powers of their milky juices. They are all more or less soporific; but the inspissated secretions of *Papaver somniferum* and its varieties are believed to afford our chief supplies of opium, although it has been asserted that the best Turkey opium is procured from the *P. orientale*; and other species are believed to be resorted to for the preparation of the drug in Persia and other oriental countries. That the *P. somniferum*, however, yields it in abundance has been proved by crops grown in this country, and the preparation here of English opium, which is reported to have been equal to that imported from India or the Levant, indeed to yield a larger quantity of morphia than that of foreign growth.

The opium trade is one of considerable importance. In 1829, says Barnett, nearly 50,000 pounds were imported into this country, of which 42,804 came directly from Turkey; 25,000 pounds were re-exported; so that the annual consumption in the United Kingdom varies from about 20,000 to 25,000 pounds. Its value in bond is seventeen or eighteen shillings per pound, and the duty is four shillings. In England opium is little used, excepting as a medicine; but in Turkey and China it has escaped from the controul of the physician, and is used largely as a luxurious stimulant, and a substitute for spirituous liquors to produce intoxication. The importation of opium into China is expressly forbidden by law, not, however, on commercial or political, but on moral grounds; but as this drug is as necessary to a Chinese mandarin as claret or Burgundy wine to an English gentleman, the contraband trade is extensive, amounting to fourteen million Spanish dollars yearly; and from it alone our Indian government derives an annual revenue of 1,800,000 sterling. Some extraordinary cases are on record of the effects produced by the continued use of opium, the ecstasies it occasions, and the deplorable condition to which it, in a short time, reduces the infatuated men who eat it; and yet, from reports collected by Professor Christian, life does not appear to be shortened, nor disease produced.

The seeds of the poppies are very numerous, each capsule containing about 32,000. They have a nutty flavour, and form a nutritious food. They abound with a bland oil, which, when expressed, may be used as a substitute for olive oil in culinary and other processes.

The *P. rhæas* is the corn poppy of Britain, and is a noxious weed among wheat. In some seasons it is much more abundant than in others, especially on light soils; its appearance, however, depending on the state of the soil when the wheat is sown; if laid in heavy, not a poppy seed will vegetate; but if light, and the farmer neglect to roll or tread the land firmly with sheep, his crop will be nearly choked with poppies, and charlock also, in the following summer.

Besides the *Papaver*, or poppy, eleven other genera are united in the order, viz., *Argemone*, *Mecynopsis*, *Hunnemannia*, *Sanguinaria*, *Bocconia*, *Machaya*, *Römeria*, *Eschscholtzia*, *Glauctum*, *Chelidonium*, and *Hypecoum*.

PAPAW TREE is the *Carica papaya* of Linnaeus, an East Indian plant, having the altitude of a tree, but the stem and foliage of an herb. It belongs to *Cucurbitaceæ*, bearing large fruit like a melon, but by

no means so good. The species grow freely in our stoves, but are infertile in consequence of the plants being unisexual.

PAPER MULBERRY is the *Morus papyrifera* of Linnæus, and *Broussonetia papyrifera* of Ventenat. A common plant in our shrubberies, known as the paper-mulberry, and propagated by layers.

PAPILIO (Linnæus). The butterfly. See the articles **DIURNA** and **BUTTERFLY**.

The genus *Papilio*, as restricted by modern authors, comprises only those species which have all the legs perfectly developed, the chrysalis girt round the middle, as well as attached by the tail (as represented in the plate of British butterflies); the palpi of the perfect insect very short, and scarcely extending beyond the forehead, with the third joint very indistinct. The species of which this genus is now composed are remarkable for their size and the splendid variety of their colours. They are found for the most part in the tropical regions of both hemispheres, three species only being inhabitants of Europe, namely, *Papilio Machaon*, *Podalirius*, and *Alexanor*.

Those species which have red spots on the side of the thorax formed the Linnæan division *Equites Trojani*; whilst those which wanted this character were named *Equites Achivi*. In many species the posterior wings are furnished with a pair of tails, whence these species are named swallow-tailed butterflies. The caterpillars are very variable in their forms, so that from a consideration of the structure of these insects in their preparatory states, it will be necessary still further to subdivide this very natural group into minor divisions or sub-genera. When alarmed, these caterpillars protrude from the upper side of the neck a fleshy forked horn-like protuberance, emitting at the same time a very disagreeable odour. The body is naked and destitute of hairs or spines.

As the two British species of this genus are the largest of our butterflies, and consequently objects of considerable interest, not only on this account, but from their beautiful appearance, we have represented them in our plate of British butterflies.

PAPILIO MACHAON (Linnæus), is of a yellow colour with a black border to the wings, in which are yellow lunules; the posterior pair tailed, with six blue spots and a red ocellus at the anal angle. It varies very considerably in size, some specimens being three inches, and others three inches and a half in the expansion of the wings. The caterpillar is green with black rings spotted with red. It feeds upon the fennel and carrot. It is by no means rare in the fens of Huntingdonshire and Cambridgeshire, where the writer has had the pleasure of seeing it in the living state.

PAPILIO PODALIRIUS (Linnæus), is about the same size as the preceding, of a paler yellow colour with black longitudinal bars, some of which are abbreviated; the posterior wings are tailed, with blue lunules and a red and black spot at the anal angle, and a red streak on the underside. This species has long been a reputed British insect, but doubts have been thrown upon its right to be considered an indigenous insect. The writer herself has, however, been informed both by the Rev. F. W. Hope and H. R. Read, Esq., that they have severally taken a specimen of this butterfly; the latter at Eton about 1826. This specimen has been figured by Mr. Curtis in his *British Entomology*.

PARASITA (Latreille; or, more correctly, *Ano-*

PLURA, Leach). An order of apterous insects, belonging to the class, *Ametabola* of MacLeay, but placed amongst true insects by Latreille, having six legs, being destitute of wings, having only simple tubercles or ocelli for eyes, and the mouth either suctional or mandibulated; the body is broad and depressed, without any terminal threads or filamentous appendages as in the *Thysanoura*. This order is composed of the Linnæan genus *Pediculus*, which see.

PARASITIC INSECTS. This name is applied to those species of insects which, in some manner or other, subsist upon or within the bodies of other insects, which they in general ultimately destroy. On examining, however, somewhat more minutely the proceedings of these parasites, it is easy to discover that there are various kinds of parasitism if we may be allowed to coin a term to express the parasitic connexion between these insects. In the *Ichneumonidae*, for instance (which see), the connexion is such, that the female parasite deposits her eggs upon, or introduces them into, the body of another insect, upon which the young, when hatched, prey. In the *Pediculidae*, on the other hand, the connexion consists in a residence upon the outside of the body of another animal, upon the humours of which the parasite feeds, without causing the death of the animal attacked; whilst in another class, namely, the cuckoo bees, and wasps, the egg is merely deposited in the already-provisioned nest of another working species nearly allied in general structure to the parasite, so that the food stored up serves either for the parasite or the insect in whose nest it is placed, the former, however, is generally developed before the latter, and, consequently, by devouring the supply of food, starves the latter to death.

Having already in various articles, given more detailed accounts of these variations in the parasitic habits of insects, we shall here merely refer the reader thereto.

PARNIDÆ (Leach). A family of coleopterous insects of small extent and minute size, belonging to the section *Pentamera*, and sub-section *Rhyphophaga*, having the antennæ very short, and clavate with a large lateral ear-shaped lobe; the legs are formed for walking; the tarsi moderately long and slender, with strong claws; the body oblong and convex, and clothed with a silken pile; the thorax is generally acute at the posterior angles. There are two genera, *Dryops* and *Parnus*, the species of which frequent the muddy banks of ponds, &c., creeping slowly about the roots of aquatic plants. The type is the *Parnus prolifericorius*, Fabricius, which is about one fourth of an inch in length, and of a dark brown colour.

PARROT (*Pittacus*, or rather *Pittacidae*, the parrot family). An exceedingly numerous and highly characteristic family of birds, belonging to the order of climbers, or those with zygodactylic feet; and from this structure, being chiefly forest birds, though some of them alight on the ground and find their food there. But the greater part are tree birds, remarkably dexterous in climbing, in which they use the bill, which is very powerful and peculiar in its shape, as a sort of third foot, or hand; for the foot of a true parrot is a grasping instrument rather than a walking one, and as such it partakes more of the nature of a hand than of that of a foot.

With the exception of a single species found in North America, and which is represented as being

much less abundant now than formerly, there are no parrots without the tropic in the northern hemisphere. It is different in the southern one; but still, though parrots occur in Australia, in Southern Africa, and in South America as high as the fifty-second degree of latitude, which answers to that of the middle of Europe, in the northern hemisphere, the country there is tropical in its vegetation, and on this account we might be prepared to expect that it should be tropical also in the character of its vegetable feeding birds, and indeed in the greater part of its living productions. That the vegetable and the animal kingdoms should be adapted to each other in every country, whatever may be the character of the country, is a law of nature from which there is never any deviation, unless in so far as man interferes with the natural state of things, by introducing artificial modes of culture.

The parrots are almost exclusively vegetable feeders; and the kernels of fruits, and the buds and flowers of trees, are the chief sources on which they depend for their nourishment. Thus they are fitted for a peculiar locality, namely, one in which there shall be for the greater part of the year a constant succession of food for them; and they could not naturally exist in those countries where the woods are for several months of the year not only flowerless and fruitless, but also leafless. The forest birds of temperate countries may be said to dwell in the forests rather than to subsist upon them. This is true of those birds of considerable size which build the highest, and congregate in the greatest numbers at the same place. The rook, for example, is in no other wise indebted to the forest in which it builds, than for dry sticks to construct its nest; and the picking up of these is a great improvement to the cleanliness and general condition of the forest. It is the same with the heron, and with all our larger birds which nestle and roost in trees.

In the tropical forests the case is very different; for the trees there supply both habitation and food to an immense number of birds; and, though different species of these feed on different substances, the parrot family may be considered as feeding upon the trees themselves; and therefore they are forest birds in a more strict and exclusive sense of the word than any other family which we can name. It is true that they are not confined to the tree, for the greater number of them are well winged and powerful flyers; but still their flight is chiefly from tree to tree, and, while the tree continues to afford an adequate supply of nourishment, the parrots climb and scramble over it with very dexterous rapidity, and scrutinise every twig with the same perseverance as ruminating animals show in browsing their pastures.

Though very many of them are noisy birds, and they are exceedingly numerous, there is really less known of the parrots in a state of nature than there is of almost any other family of birds, and especially of any family which is so numerous. The character of the tropical forests causes this, from the difficulty with which masses of such tall and thickly matted vegetation can be entered, and the impossibility of seeing what is going on, even after an entrance has been made. We know that they do inhabit the forests, that their principal food is vegetable, that they nestle chiefly in the holes of trees, and that they are very noisy withal; but these matters, which amount to very little, constitute almost the

whole of their history in wild nature, as known to man.

In their natural state, many of them are social birds, often issuing from the trees in large flocks, and laying the cultivated fields under pretty severe contribution. Social birds are almost always susceptible of being tamed in nearly the same ratio as they are social, and the parrot family do not form an exception to this. Some of them are much wilder than others, and all of them are inclined to make very wanton use of their bills, in tearing to pieces furniture and other wooden substances; but many of them are capable of showing a very considerable degree of attachment to those who feed and are otherwise kind to them. Generally speaking, also, they suffer less from confinement in cages than most other birds, because their climbing propensities enable them to take a great deal of exercise even in a confined space. Their plumage too is not easily ruffled; it is less so indeed than that of perhaps any other birds; and thus if a parrot is properly fed, and enjoys wholesome air in not too cold a temperature, there is seldom any thing the matter with it; and, under such circumstances, it may be kept under confinement for a great many years.

Since a general intercourse was established between Europe and the tropical countries, more live parrots have been introduced than of any other tropical birds, or indeed of any other tropical animals whatever. In addition to the brilliant plumage and lively manner of most of the parrots, many of them are easily taught to pronounce words and sentences, and also to whistle tunes with clearness and precision. Some of those writers who endeavour to give an apparent interest to their style, by elevating the animals to a rank resembling, if not equalling, that of man, have supposed that there is some sort of speculation in these birds; and that they suit not only their natural attitudes and sounds to the circumstances under which they are placed, but do the same with those words and sentences which they are artificially taught to imitate. There is of course no truth whatever in the analogy which is thus attempted to be established. The parrot of course understands not one word of what it utters, and therefore, when it appears to give appropriate answers to questions, or to make remarks applicable to the occasions on which they are uttered, it merely obeys the circumstances under which it is placed; and it is our ignorance of many of those circumstances which makes us fancy that the bird suits the word to the occasion. Though this sort of prejudice has been held by many, it has never been strong enough for becoming general with the public; for, on the other hand, "parrotting" has become the name of that repetition of mere words by human beings when the repeaters are utterly ignorant of the meanings of those words. We shall afterwards, most probably, have occasion to remark that there has been a good deal of this parrotting in the attempted natural history of the parrots themselves, a circumstance which is perhaps unavoidable, on account of the very little which is known of the natural history of the birds, or of the differences of habit between those which are different in appearance.

Still, the facility with which parrots can be made to speak, to sing, and to whistle, renders them very amusing birds; and is a proof that, though all their resources are of course purely animal, they are better endowed in this respect than many other birds. Their

habits in a state of nature would naturally lead us to suppose this, for a parrot in the woods is a very hard-working creature; and in order that it may find its own food, and in so doing keep down that luxuriance of the tropical fruit by which it would otherwise be checked by the very excess of its own growth, it has harder labour to perform than almost any other bird which feeds upon vegetable matter. Any one who looks at a stately tree, in that season when it is naked of leaves, and the ramifications can be seen to their ultimate terminations, must be aware how perfectly beyond all the powers of arithmetic the buds of such a tree are. But the trees of tropical forests are much taller than ours: and, though the palms and several others rise with a single bud, and have only a crown of leaves, or more strictly speaking fronds, still there are stately branchers which cover thousands of square miles in the tropical countries. Many of the most luxuriant of these grow in marshes, in the water of slow running rivers, and even in the sea, so that they are not accessible in any way but through the medium of the air, and, except on the trees themselves, there is no resting place for the foot of any inhabitant of the air. Such places are the grand haunts of the parrots, because in them there is a constant supply of water and of heat sufficient for any kind of vegetable growth, and thus they know no winter. Such places are the head-quarters of many tribes of the parrots; and they are understood to breed at least twice in the year, without any absolutely fixed season for the operation. Little, however, can be known of their economy in such places, for the ground is impassable, the air is pestilent to human beings, and a traveller who should attempt to explore such a forest would never return to publish the tale of his adventures. It is understood, however, that even those species which quit the woods seasonally in flocks, at least for part of the day, live in pairs during their breeding times; and that, generally speaking, sitting on the eggs and the feeding of the young until able to provide for themselves, are the only domestic labours of the birds. As was hinted, they nestle in the holes of decayed trees. There are many such in these forests; because if there was not a decay proportionate to the growth, the forest would soon monopolise everything else, and end by choking itself. It is highly probable that the parrots contribute not a little to the ridding of those forests of the dead trees, by enlarging the holes in their trunks, and so letting in the rain, by which the tree is very speedily reduced to dust. This is an exceedingly probable inference from the disposition which they show to gnaw and divide into chips every piece of wood which they can reach. This is not done for the purpose of gratifying their appetite, for none of them show the least disposition to eat wood. It is, however, so very general among them, and they themselves are so numerous, that they must practise it in their natural state, and it must answer some purpose in nature corresponding to the exertion which it calls for on their part. It is clearly not a habit acquired in confinement, neither is it the result of any attempt on their part to regain the state of freedom. Parrots, if properly fed, are less impatient of confinement than almost any other birds; and when a parrot has free range of an apartment, it very soon begins to exercise its powerful mandibles upon the chairs and other furniture. We naturally look upon this as wantonness; but animals have no wanton habits. The law

of material nature is upon them in everything they do; they have no power of resisting that law, and therefore every natural operation which they perform answers some natural purpose, whether that purpose happens to be known to us or not.

Many accounts have been given of the loquacity of parrots; and some of them are very amusing, as showing the power of imitation and the perfection of execution hereafter to be noticed. We shall content ourselves with little more than a single one, which we give from personal observation. The writer of this article, had a friend who received a green Amazonian parrot from a naval officer, who had just returned from the command of a frigate on the West India station, during the time when the West Indian seas were so much infested by pirates. This parrot had been taken from a piratical vessel made prize of by the frigate; and as it was docile, and actually communicated some useful hints in the scraps of Portuguese which it repeated, and sung and whistled in loud and clear strains, it soon became a favourite on board the frigate, and was not long in learning all the pipings and words of command which were most frequently repeated.

On the evening of its arrival, its new master had a dinner party, and, the parrot being a stranger, was placed on a pier table at the lower end of the room. From the time of its landing it had continued quite silent; and, as the giver had not said one word of its powers, it was supposed to be a dumb parrot. The party sat down to dinner with a good deal of glee and hilarity, and the bird began to show more activity. In a short time it piped the boatswain's whistle, till all the apartment rung again; and almost immediately after the pipe, it called in a hoarse stentorian voice—"Steady! take in a little there," which somewhat astonished the party, as they were taking in their dinner and wine. During the afternoon it kept calling, "One point below!" "Thus." After a while it treated them with a very tolerable repetition of the Portuguese hymn, and concluded by a violent fit of swearing in the same language. The age of this specimen when it came into the hands of the gentleman alluded to was not known, neither is the writer acquainted with the sequel of its history, but it was a very amusing bird, though quite wayward and untractable.

Though there are considerable differences between the sections and genera, into which the describers of them in detail have divided the parrot family, yet there are certain general characters which belong to the whole, and point them out as being more distinct and true to a family likeness than perhaps any other family of birds. The number of species is so great, and so little is known of them, except differences of size, shape, and colour, that the details could not be made intelligible, or in the least interesting to any ordinary reader; we must therefore confine our observations to a comparatively small number.

Their general characters are: the bill short, thick, swelling, very hard and strong, compressed, convex in the outlines of both mandibles; broad at the base of the upper mandible, but compressed toward the tip, which forms a hook over the end of the lower one, very hard and sharp, and more or less awl-shaped at the point; it is also provided with a cere at the base; the lower mandible is short, recurved upwards at its extremity, and obtuse; these mandibles close with great force, and the lower one is provided with a set

of very powerful muscles, and has a sort of lateral grinding motion, as well as a shutting and opening one: in general, the lower mandible has a sort of tooth-like points; the nostrils are pierced in the cere, and they are open and round; the feet are in general short, with the tarsi very stout, but shorter in the generality of the number than the external front toes; the toes are four in number, two to the front and two to the rear, the former united by a small membrane at the base; the latter entirely free, and the outer toe of each pair longer than the inner one; the wings are generally of mean length, but very strong, and capable of rapid flight; the first three quills are nearly equal in length, and, like all the plumage of the birds, they have remarkably firm webs: generally speaking, also, the feathers on the upper part of the body are large and firm, and appear like a covering of scales, often of the finest gloss and the richest colours.

Among birds so numerous, differing so much in their size and forms, and extending fairly round the globe in its equatorial parts, it is difficult to give a general description of their manners. Most species of them are very abundant; and in those forests which form their principal habitats, the quantity of vegetable matter which they consume and also destroy, would appear perfectly incredible to any one accustomed to the habits of birds of temperate countries only. In these forests each one tumbles to the ground many times the quantity of food which it really eats. A few build their nests in the tops of the loftiest trees, where they work the branches and twigs together with a good deal of art; but the greater part place them in the holes of trees. The eggs vary from two to four, and are of a white colour in most of the species. The female sits very constantly; but at those times when feeding or exercise requires her to go out, the male is always at hand to take her place. The young are understood to eat buds and little soft fruits which are brought them by the parents. It is generally understood that the leaves of common parsley, which most animals can eat with impunity, are a mortal poison to parrots.

In their native forests they are exceedingly noisy birds, but it does not appear that any of them have much tendency to attack any other bird or animal. The groups nearest to which they are placed in the systems eat eggs and insects; but it does not appear that the parrots have this tendency, nor are they quarrelsome with each other. There is little doubt that the manners of parrots in their native woods differ greatly from those which they display when kept in a state of captivity by man. Numerous as they are, they belong to wild nature, and their use to man is limited. It is true that the young birds generally, and also the old ones of some of the species, are eaten by the human inhabitants of some of their localities. But there are few human inhabitants in such places; and it is no very easy matter to come at the parrots unless when they flock out upon plantations near the woods; and upon such occasions their carcasses do not repay the damage they commit.

From the scanty information which we have respecting them, the classification of these birds is in a very imperfect state; and though various ornithologists have formed elaborate systems of them, those systems are hardly intelligible to ordinary readers, and not of much interest or use to anybody. As is the case upon subjects where the truth cannot be

obtained, every one has proposed a method of his own, and with very few exceptions, it may be said, that one of them is just as good as another.

It is not possible to form even a geographical arrangement of them which can be applied to any useful purpose; for we find great dissimilarity in the more essential points between species which inhabit the same locality, and great likenesses between those which live at each others antipodes.

In all their varieties, whether of genus or species, parrots are, strictly speaking, day birds, going to their repose at sunset, and being up with the sun again in the morning. As already hinted, the whole may be said to live upon vegetable food. In the greater number this food is the kernels of fruits, of which the birds appear to care little for the pulpy pericarp, or portion which we term fruit, how highly soever we may esteem it for its flavour. Fruits which have large seeds inclosed in a hard shell or nut within the pericarp, are the favourites with them. They find these upon many of the palms, upon the wild almonds, and upon various other trees; and the dexterity which they show in opening the valves of even the hardest of these shells is truly wonderful. It is not done by mere random force, but by an application of the bill as perfect as if it were guided by human science, or even more so. When the shell and kernel are divested of whatever external covering they may naturally have, the whole is brought against the hook of the upper mandible on the one part, and the end of the tongue on the other, into the very best position for enabling the application of the lower mandible to separate the valves. This is done, of course, by the simple touch of the tongue in the bird, for the horny part of the bill has no sensibility, and it is impossible that any use can be made of the eye or any other organ of sense. Notwithstanding this, it would be impossible for man, using both his eyes and his hands, to place the substance to greater advantage for the action of the instrument; and thus the parrot is enabled to break the shell and get at the kernel, with the very minimum of labour. When the shell is broken, the tongue still keeps the kernel against the hook of the upper mandible, and thus allows the lower one to be opened, so that the fragments of the shell may be rejected.

For the accomplishment of the double purpose of this curious bill, it is not only provided, as formerly stated, with very strong muscles, but there is a provision made for preventing that concussion which arises from its powerful and frequent action, from being communicated to the brain. This is obtained by the upper mandible being articulated with the bones of the cranium, and not united. In consequence of this, the upper mandible is susceptible of some motion on its base; and this motion not only prevents the concussion from being propagated to the brain, but enables this organ to exert a much more powerful effect than it would have, if the upper mandible were so firmly united at its base as to be incapable of motion. As the bill is actually constructed, the upper mandible partially descends to meet the lower one, and thus no power whatever is lost, and so the bird is enabled to take even its hard food with ease compared with what other birds have to undergo. This is a very general provision in Nature's mechanical structures, for we meet with it in the feet of swift-leaping animals, in wings, and, in short, in every organ of powerful motion. If the organ is to be ex-

erted with more than ordinary vigour, there is always some flexibility provided in its base by peculiarly shaped bones, the cartilaginous substances of which slide upon each other by cartilage or ligament, which confines the shock to the single organ, and prevents it from being so propagated as to affect the vital parts of the animal. This is a provision of Nature which mankind would do well to imitate as far as possible in all those machines which work with great power, in order to prevent the machine from being shaken to pieces by the violence of its own working, which can be much better done in this way than by any addition of mere mechanical strength.

Some of the family, which live more habitually on the ground than the typical parrots, have not the bill of the same large size or powerful construction; and these are understood to feed, in great part at least, upon succulent and bulbous roots. They still have the feet zygodactylic, a character which is not departed from in any of the family; but they have much less motion of the joints by which the lower end of the tarsus is articulated to the toes than the climbing parrots have. In these this articulation is so loose, that when the birds attempt to walk on a level surface, the foot is so much turned out, that the tarsus appears to be applied to the inner edge of it, and not to the upper side as it is in those birds which are more characteristic walkers. This turn outwards in the foot is eminently characteristic of a climbing instrument; for we meet with it in all the ape and monkey tribes; and the joint is always the looser and more oblique, the more constant the climbing habit is in the owner. This of course enables the animal to have a much greater range in the action of the prehensile part of the organ, than if the joint were firm, because, by means of it the foot can be turned in a greater number of directions, and especially laterally outwards, which is the most favourable direction for the foot of a bird which scrambles among the branches. The ground parrots, which are rarely if ever upon trees, have feet of a different construction. In them the tarsi are much longer in proportion, and the articulations of the toes together are firmer. They are also much more slender in proportion to the weight of the birds, and neither the muscles which give motion to the toes, nor the connecting tendons by means of which the action of those muscles is carried to its proper place, are nearly so powerful. So much power is not indeed required; for the ground parrot has only to walk, whereas the tree parrot has often to suspend itself in all positions by a single foot, often by a single toe, and to perform many operations in seeking its food while it hangs in these positions. It is impossible to avoid admiring the admirable perfection with which in these cases, and, indeed, in every case where we have the means of observing, the degree of power in an instrument is adapted to the necessity that there is for this power, no matter how fine the shade of distinction and habit may be; for we find that the shades of adaptation are always equal to it. It would be endless, however, to point out all the peculiarities of a race of birds which are so varied in their forms and their manners, though so constant to their general type, and of which all the members are equally well adapted to the places which they hold in nature. Those who have examined the tropical forests, mention that there appears to be a species of parrot adapted for each of the more conspicuous kinds of trees which are to be met with in those forests. Thus, if the tree is a palm, or any

thing else which has a single stem, and can afford nourishment for a bird only at or near the top of that stem, then the species of parrot set over it to consume the surplus of its fruit, is an air bird, capable of flying over the forest in search of such trees; and when such is the case, the body of the bird is lighter in proportion to its lineal dimensions, and its tail is generally very much produced, which assists it in ascending and descending. On the other hand, the short-flighted parrots, which inhabit trees which are very much branched, and bear fruit in the axillæ of the leaves of the smaller twigs, have the bodies stouter in proportion to the dimensions, the tail shorter, and the feathers more firm and scaly. Parrots of this last description inhabit regions which are more perennially fertile than those inhabited by the former, whose more produced flying feathers and lighter bodies, and, generally speaking, also their more vigorous make, fit them better for ranging into a new locality when food fails them in the old one, and also for making daily excursions of considerable length over the fields in the vicinity of those trees wherein they roost during the night. It is these discursive ones which are most destructive to plantations in the neighbourhood of the woods; and as they invariably make their excursions in large flocks, and destroy much more than they eat, their visits are always peculiarly annoying to the planters. We shall hereafter have occasion to allude to some of the species which are troublesome in this way. The tree parrots with short tails, which are the characteristic ones, are also those that can be taught to articulate words in the greatest number, and with most distinctness. Their range on the wing is considerably more limited than that of the long feathered ones; but still, though their flights are usually short, their wings are powerful. The wing of no parrot is, however, constructed after that fashion by which a bird can be kept in the atmosphere for a very great length of time. In order that a wing may be adapted in the most perfect manner for this purpose, there is an element necessary in addition to strength of muscles and firmness of feathers, namely, the power of taking a hold on the air by the fibrous terminations of the webs of the feathers, especially those of the under sides of the wings. Parrots of long flight are a little better furnished in this respect than short-flighted ones; but still all of them have hard feathers as compared with those of birds which range greatly through the air.

We have said that there is some confusion in the systematic arrangement of these highly interesting birds; and that the ablest systematists are at issue with each other on the subject. There may, in some instances, be faults on the part of those systematists; but the grand difficulty, of which none of them can get the better, is the want of information, not merely with regard to the shapes, colours, long or short tails, large or small bills, naked or feathered cheeks, or any of the other peculiarities which are usually made grounds of specific distinction, but with regard to the use of the birds in the economy of nature, and how the use of one varies from that of another. Buffon, whose eloquence tended so powerfully to draw the attention of mankind to natural history, and whose errors in fact, and more especially in hypothesis, have tended so much to distract that attention, that it is not easy to say whether upon the whole he did more good or harm to natural history, made a sort of geographical division of the parrots. His primary separation was into the parrots of the eastern continent

and those of the western. Each of these he again divided into seven families, placing the cockatoos at the head of the eastern grand division, and the maccaws at the head of the western. Such an arrangement, however, possesses no advantage; because, though there is not perhaps exactly the same species in the east and in America, yet in each continent there are some species approaching much more nearly to those of the other than some of those of either continent approach each other. This arrangement must therefore be abandoned, as indeed every arrangement which is merely geographical must be, unless cause is shown in the different characters and productions of the countries which are contrasted. Now Buffon had some crotchets on the subject of the differences between the physical condition of the eastern and the western continents, which cannot be admitted into any system, the object of which is either the establishment or the promotion of scientific truth.

Perhaps one of the best arrangements of the parrots is that made by Kuhl, who divides the whole family into six divisions. These agree pretty nearly with the common names which have been given to the birds in English, which is always an advantage when it can be adopted. These divisions, according to Kuhl's arrangement, are maccaws which have the tail long and wedge-shaped, and the cheeks naked of feathers. Of these we have already given a very slight general notice in the article *Ara*, though without enumerating any of the species. The second division are the long-tailed parrots, some of which have a naked space round the eyes, and some not; and those which have such a space are not unfrequently styled maccaw parrots, as being, in this respect at least, and also in the general form of their bodies, something intermediate between the maccaws and the true parrots. The members of this division, which have the cheeks naked in part round the eyes, are, almost without exception, natives of South America, and especially of Brazil, the grand head-quarters of the maccaws; though one at least is found in Western Africa. Those which have the cheeks completely feathered round the eyes are, without exception, natives of the eastern continent, over which they take a very wide range, being found in Western Africa, in tropical Asia, in the oriental islands, and in New Holland. The third division consists of birds which are of smaller size, having the tails very short, and either round or pointed. They are confined to the eastern continent and the isles of the Pacific. The fourth division consists of the parrots properly so called, which have the tails of moderate length, or rather short, and, generally speaking, squared over at the termination. Birds of this division seem more widely distributed than any of the rest. They are plentiful in tropical America; they occur also in Western Africa; they are found at the Cape of Good Hope; they are found in the West India islands; and also throughout the isles of the east. These are the parrots properly so called, or the true parrots by way of eminence; and, as we already hinted, they are found on richer pastures than any of the rest; they are perhaps not so elegant in their forms as some of the others, but, taking them altogether, they appear to be birds of greater resource, are more docile in confinement, and many of them can be made to articulate better. The fifth division in this mode of arrangement comprises the cockatoos, which have the tail squared over, the cheeks covered over with fea-

thers, and a crest of feathers on the head, which they are capable of erecting or flattening at pleasure; they are almost, if not altogether, natives of Australia. The sixth division, according to Kuhl, have the tail even, and the cheeks naked, and are without any crest. From this enumeration of them, it will be seen that very little information can be conveyed by these divisions, which are perfectly artificial, and each of them embraces birds differing as much in their habits as some which are placed in different divisions.

When we take the more modern attempts at a natural division of this family of birds, we are not better off; because there is introduced into them the QUINARY hypothesis, or that which supposes things to have been created in fives, forming a sort of circle, in which the end comes round and meets the beginning, in a way which the abettors of the hypothesis appear to be incapable of explaining, and which, in all probability, they do not exactly understand. If, therefore, we wish to understand anything correctly about the parrots, we must really go to the common names under which we group them, and to the study of the species for such information as that may afford. On the plate PARROTS there will be found figures of four species, characteristic of an equal number of those divisions into which the family is usually separated; and all that our limits will permit us to add will be short notices of only a few of the species; for their numbers are so great that even the list of them would far exceed our limits.

MACCAWS. Besides the name *Ara*, to which we have already alluded, these birds have been called *Macrocerus*, from the large naked space on the cheek and around the eye, or rather perhaps from the great length of the tail; and in this sense of the word it is usually restricted to the larger ones, which are exclusively American, and less confined to the depths of the forests than the tree birds. They have the bill rather short, and much compressed laterally, but deep as seen in profile, and of great power. The upper mandible is very much hooked, with the tip descending far over the extremity of the under one, which is also particularly strong, and so formed that its cutting edge acts nearly at right angles against the upper. The parts that act against each other are very much ruffled, so that the bill is very powerful as a crushing instrument; it keeps a firm hold of those nuts and other hard inclosures of kernels upon which the birds feed. The wings are in themselves rather more than of mean length, and they are very much pointed; but the tails are so long that they take off from the apparent length of the wings. The tail is also very much staged or graduated; and all the upper plumage of the birds is remarkably firm. The tarsi are very short; but both they and the toes are strong and admirably formed for climbing. They are decidedly tree birds; but they are pretty discursive in their flights from one part of the forest to another. They nestle in the holes of trees, and the hatch is said to consist of only two; but how many are produced in the year is not known. In a state of nature the voices of maccaws are very loud, harsh, and discordant; and, as they can be taught to articulate with difficulty, and then only a few words or syllables, they are not so much in request as the true parrots with short tails, or as some of the smaller of the long-tailed species. They are handsome birds, however, and very hardy; and, therefore, notwith-

standing the offensive noise that they make, they are often tolerated as ornamental birds out of doors, where they are very bold in defending themselves.

The Great Green Maccau (*M. militaris*) is one of the largest species, and far from being the least handsome. It is not, however, the very largest of the whole; for some of them exceed it, though the excess is more in the length of the tail than in the size of the body. The bill is dark-coloured, generally very deep blackish brown, and remarkable for its strength; the claws are also black, and very strong and worked; the colours are fine in the tint, and decidedly marked; the naked parts round the eyes and on the cheeks are flesh-coloured, marked, especially toward the under part, with slight longitudinal curves of blackish brown feathers. The eyes show very remarkably in this species; for the iris consists of a double circle, the external one bright yellow, and the internal a sort of sage green. The front is very rich crimson in rather a narrow band; and the feathers on the chin are reddish brown, passing gradually into bright green, which is the general colour of the breast and belly. The plumage on the upper part is a varying colour, appearing green in some lights and azure in others, both of which are very lively. The rump and upper coverts of the tail, and also the quills and greater coverts of the wings, are bright blue; the tail feathers are scarlet on the upper part, with the exception of a portion at the tips; and the under sides of the wings and tail are orange-yellow.

This bird is an inhabitant of tropical America, extending from Mexico to the base of the Andes; and, though it cannot be called a mountain bird properly speaking, it inhabits at greater elevations than many others of the tribe, being met with on the secondary hills at considerably more than half a mile above the sea. These birds are very numerous; and, though they breed each pair apart in the hole of a tree, they assemble in flocks at those times when they have not young, which are generally the times when their forest pastures are least productive. As long as provision is to be found upon these, they subsist upon it, eating indiscriminately the fruits and the succulent flowers, which latter, upon some of the tropical trees, contain a good deal of nourishment; the honey with which the nectaries of many such flowers abound is, however, the probable inducement which the birds have to tear the flowers to pieces. Many birds are fond of sweet substances; the parrots, taken as a family, are especially so; and some of the small species which inhabit the rich perennial forests of the eastern world are understood to feed much upon the honey of flowers. When their supply in the forest fails they are said to sally forth in very numerous flocks, at which times they attack the plantations of the inhabitants, especially those of Indian corn, upon which they commit very serious depredations. Upon these their predatory excursions, they conduct themselves with great vigilance, and always place one sentinel or more upon the tops of lofty trees. These sentinels, which are relieved by turns by others of the birds, are said to keep a sharp look out, and to detect the appearance of danger, while it is still far distant from the plunderers. Upon perceiving it they give a very loud alarm call, which is at once responded to by the rest, and the whole are instantly on the wing, and soaring above the reach of any ordinary missile weapon. January and February are the times during which they make their appearance upon the

plantations in the central parts of America; and when the rains set in they betake themselves to the forests, and live upon the bounty which nature there so amply provides for them. As game, these birds would be of comparatively little value; for their flesh is black and hard, and unsavoury to the taste; and those inhabitants who are near their haunts have no alternative but to submit to their depredations with as good a grace as they can.

Scarlet and Blue Maccau (*M. Macao*). This is also a large species, and remarkable for the brilliancy of its colours. It measures upwards of two feet and a half in length. The prevailing colour is scarlet, the wings blue, and the wing-coverts variously marked with yellow; the tail bright red, with blue margins to the feathers; the naked parts of the cheeks are white and very much wrinkled; and the upper mandible of the bill is also white. They inhabit the same part of the world as the last-mentioned species, namely, the tropical parts of South America. They do not, however, inhabit exactly the same localities; but dwell deeper in the forests, make the different species of palms their principal residence, and feed in great part upon the fruit of these. They are never found in so dry situations as the former species; and they do not commit the same extensive depredations upon the planted fields. It is also said that they do not flock so often; though, when they do, their flocks are exceedingly clamorous. They always choose high perches; and, when reposing, they are generally on the summits of the highest trees. They are rather discursive during the day, ranging about for several miles; but as night begins to set in they return to their habitual resting-places, as regularly as the rooks. They build in hollow trees, and line their nests with feathers. The eggs in each hatch, for there are understood to be two in the year, are two in number, about the size of the egg of a pigeon, and mottled something like those of a partridge. The time of the incubation is not distinctly known; but it is well ascertained that both parent birds are remarkably attentive to their offspring. They sit alternately, so that as one goes out to feed, the other invariably takes its place; and, after the young are hatched, the old birds nurse them with great attention, until they are able to provide for themselves. The feeding of the young, like their own feeding, is wholly conducted in the light of day; and at night, and also when he rests during the day, the male takes up his perch very near the nest. By means of this constant habit of theirs, the nest is not difficult to be discovered; only it is very often over the damp and swampy grounds, where the footing is bad and the forest very much tangled. The young birds are susceptible of being tamed, though they never become very tractable; and they may be made to articulate a few words, but not distinctly. Comparatively speaking, they are hardy birds in confinement, and live to a great age. When the old ones are confined they are exceedingly mischievous; and, if kept in a room, their chief occupation consists in pulling the furniture to pieces; and, so hard is their bill, and so dexterous are they in the use of it, that they can draw nails with it, if the heads are such that they can get a proper hold of them. Their flesh, like that of the former species, is hard, dark-coloured, and unpleasant to the taste of a European; but still the Indians, the negroes, and even the poorer white inhabitants of South America, contrive to use it

in considerable quantities as an ingredient in their soups. It is reported, that, when they feed upon certain poisonous plants, the manchineel, for instance, their flesh becomes poisonous, though the fruit does not hurt them. It is probable, however, that this is exaggerated in the same manner as the deadly qualities of the manchineel tree itself have been exaggerated. There is no doubt that both the fruit and the juice of this tree are exceedingly acrid; and that a portion of the concentrated juice, inserted into a wound, would produce death; but there is no truth in the old story of the odour given out by the tree and the water dripping from it being poisonous. It is certain, however, that the juice of this tree was at one time made use of, by the French colonists in America, for the purpose of inflicting a most barbarous torture upon their slaves. The scourges, with which they lashed those unfortunate creatures, were prepared by being steeped in the juice of manchineel; and thus every blow inflicted by the scourge caused the same agony as if that scourge had been red-hot iron. Acridity appears to be the leading character of all parts of the manchineel; and therefore it can hardly be supposed that these macaws, which have soft fleshy tongues, and, as one naturally supposes, a pretty keen sense of taste, would feed upon it. In the case of all those marvellous stories, which are told about birds and other animals eating poisonous substances, and becoming poisonous themselves in consequence of so doing, it is necessary to exercise a due degree of caution before we give credit to them.

Aracanga Macaw (M. Aracanga). This species bears considerable resemblance to the last-mentioned; and the two have sometimes been confounded with each other under the common name of red and blue macaw. Red and blue are certainly the prevailing colours of both; but the red upon this one is of a different tint from that on the former, inclining more to crimson than to scarlet. The authorities are not agreed as to the size, some describing it as smaller than the scarlet and blue species, and some as larger. We believe the specimens of it differ very considerably in size, and that the principal difference of dimensions is in the length of the tail, which, in healthy birds, is about twice as long as the body, that is, rather more than two feet in length. When the bird is in bad health, this member is shorter, and has not the firm and decided character by which the full vigour of the bird is indicated. In such cases, also, the general plumage loses the greater part of its gloss, and the bird is, altogether, very inferior in appearance. The bill is very large and powerful, like that of the preceding species; but the upper mandible, instead of being white, is pale lemon yellow, with the exception of a dusky spot at each angle of the gape; and the under mandible is black, or nearly so. The naked space on the cheeks is covered with pale pink skin, puckered and wrinkled, so that it has something the appearance of scales, but without any longitudinal arches of small feathers; the feathered part of the head, the neck, the scapulars, the back, the breast, and the belly, are dark red; the middle coverts of the wings are bright yellow, tipped with greenish blue; the bastard wings and the quills are deep azure; the rump and upper and under coverts of the tail are of the same colour, but considerably paler, and with a shade of purple; the tail is very handsome, consisting of four middle feathers

of deep red, a red and blue one on each side of these, and the remaining ones altogether blue. This, however, is the marking of the upper side only, for the under side of the tail is wholly deep red, which contrasts beautifully with the pale blue of the under tail-coverts.

This bird is found in the same localities as the one last mentioned, and, from the accounts, it appears to be equally abundant. In all its habits, indeed, it bears so close a resemblance to the former, that a description of the one will serve for that of the other, with the exception of the particulars which we have stated. As is the case with all the macaws, this species is not impatient of captivity, provided that it is duly fed. It is a magnificent bird both in size and in plumage, but it is a bird of comparatively little resource, and susceptible of only a very slight degree of education. For this reason, it is not at all adapted for being a pet bird; and in the house it is intolerable, both on account of the use which it makes of its powerful bill in the work of destruction, and of the loudness and harshness of its screaming. In large collections, however, where birds or other animals are kept, or professed to be kept, as much as possible, in a state of nature, it is highly ornamental; and there are few birds in the collection of the Zoological Society of London which draw more attention on account of their mere size, form, and plumage, than a specimen of this macaw. It should seem that the colour of this species is not absolutely constant, for specimens have been mentioned in which the shoulder and lower part of the neck had a yellowish tinge. There is, indeed, a good deal of uncertainty about the describing of any of the parrot race entirely from their colours; and yet, in the species which are nearly allied to each other in size and in habit, the colours are almost the only means of distinction that can be made use of. Hence the description, how carefully soever it may be drawn up, can seldom be made anything more than an account of a single individual; and it very often happens that this account will not apply to the very next individual with which one meets.

Blue and Yellow Macaw (M. aracana). This is a handsome species, though very different in the colours of its plumage from those which have been mentioned. It is also susceptible of a little more education, and therefore it is the macaw which we most frequently meet with about the houses of those who are fond of keeping ornamental birds. It can be taught to articulate, though very sparingly, and with little distinctness. It is, however, much more obedient to the calls of those about it, and shows more sensibility to kind treatment than most of the macaws; nor does it appear to be so incessantly fond of pulling to pieces everything that comes within its reach. Like the others, it is a native of the richer parts of intertropical America, Brazil, the valley of the Amazon, and the forests interior of the settlements along the southern shore of the Caribbean Sea. It is fond of rich and marshy places, where it roosts generally on the tall palm trees, and lives in great part on their fruit. As is the case with its congeners, it generally keeps in pairs, or, at most, in the little family pack, for a short time after the young are capable of using the wing. This appears to be a general habit with all birds which reside in the perennially rich places of the tropical forests. It sometimes happens, however, that the rains fall, or

Prince Maximilian Macaw

Imperial Parrot

Cockatoo

Crested Parrakeet

are later in coming than usual, and at such times the forest supply gives way, and their closest inhabitants are compelled to range abroad for subsistence. This is sometimes the case with the blue and yellow macaws; and when it is the case, they assemble in flocks, take a lofty flight, and give notice of their approach by the loudness of their scream. They are birds of very powerful wing, and have much command of themselves in the air. Their wings are very pointed, and their tails are exceedingly long, stiff, and wedge-shaped; hence they are enabled to leap about in the air with the same apparent ease as if they were leaping from one solid perch to another. They less frequently invade the plantations than some of the species already mentioned; but when they do, they are equally destructive. When they alight on their journeys, in order to rest for the night, or for a time, it is always on the tops of the loftiest trees; and they never alight without wheeling round and round in the air, as if in order to ascertain if any danger is near, before they take their repose; and while they are reposing, it is generally understood that they have a watch set, which never fails to give timely warning in case of necessity. In the construction of their nests, and the whole of their domestic economy, they bear so close a resemblance to the other species of macaws, that it is not necessary to enter into any particulars. Perhaps, indeed, there are no birds so similar to each other in their domestic habits as all the species of the macaws. They all nestle in the holes of trees—have two hatches in the year—two birds in each hatch—and are remarkably watchful both of the eggs and the young.

This, though not the largest of the macaws, is a large species, measuring upwards of three feet in length, two feet of which is occupied by the tail. The bill, which is very large and strong, is altogether of a black colour, and remarkably hooked and pointed in the upper mandible; the culmen of that mandible, which begins to curve down immediately at its junction with the forehead, measures more than three inches in length; the lower mandible is very short in proportion, but it is exceedingly firm and strong, and toothed at the extremity; the naked skin on the cheeks, which extends in a narrow line along the base of the bill, and in a point toward the ear-cover, is white, but under the eye it is marked by slender curved lines of black feathers, having their curvature directed downwards; the irides are yellowish white, so that the eyes of this species appear less conspicuous than those of many of the others; but still, from its vigilance, and the readiness with which it perceives an enemy, or a proper resting-place, there can be no doubt that its sight is very keen; above the narrow white band the forehead is green, passing gradually into blue about the middle of the top of the head, and then the whole of the upper part is a very rich and beautiful blue; on the neck this blue is rather narrow, and the outline is broken on the scapulars, but, from the turn of the wings backward, it is well defined; on the rump, and some of the smaller coverts of the wings, there is a greenish tinge; and indeed the whole upper plumage varies a little toward green in some lights, with the exception of the primary quills and tail-feathers, which have a shade of purple; all the under part is rich brownish yellow, with the exception of a band of black, which immediately surrounds the base of the

lower mandible, and extends back about half way as far as the naked white space on the cheeks, giving the bird, when seen in profile, something the appearance of having three mandibles, a large one above, a large one below, and a smaller one in the middle; the yellow which marks the under part of the body extends also to the whole undersides of the wings and tail, so that, seen from above, the bird seems entirely blue, and, seen from below, as entirely yellow; the feet are dusky, but the scales, from their being picked out with white edges, give them a mottled appearance.

Green Brazilian Macaw, or Maracana (M. Severus).—This is a small species, and may perhaps be regarded as forming a transition from the larger macaws, or macaws properly so called, to the macaw parrots. Its cheeks are naked, its forehead purple brown, and the rest of the body plumage green. The wings and tail-feathers are blue on the upper side, and dull red below. It is not larger in the body than a pigeon, being only about seventeen inches in length. It is a native of Brazil, where it occurs in numerous flocks, which do a great deal of mischief to the coffee plantations; though it is the pulp of the coffee berry which it eats, and not the seed or part which is used in commerce. It is much more familiar than the larger macaws, and visits the cultivated grounds much more frequently. It is also a bird of very inferior wing, and capable of taking only short flights. It is easily kept in a state of domestication, and very fond of being petted; but it is jealous and bad tempered, showing great hostility to strangers, and especially to children. If any one is made to share the attention bestowed on it, it is worked into a paroxysm of rage, attempts to fly at them, and bite and scratch, and never rests satisfied while those who are in the habit of caressing it pay attention to any other living creature. Its jealousy extends even to the other members of the parrot family, and it is seldom satisfied if any of the rest of them are in the room with it. Thus, though it is rather a handsome bird, it is unpleasant to keep in a collection among others; and as its powers of articulation are very limited, it is of no great value even to the curious, when kept singly. When, however, it enjoys the whole attention of those who fondle it, it can be amusing; and it expresses satisfaction in a peculiarly soft sort of murmur, and occasionally utters a sound having some resemblance to a laugh.

Prince Maximilian's Macaw (M. hyacinthus), is another Brazilian species, of rather larger size, and rich in its plumage. It is about twenty-eight inches in length; and this may be reckoned about the average size of the macaws properly so called. Its general plumage is very rich hyacinth blue; the quills and tail-feathers are violet blue, with green reflections. There is a yellow spot at the angle of the gape, and the naked skin round the eyes, and also the feathers on the chin, are the same colour. The bill and feet are black. This species is darker in the general tint of its plumage than most of the macaws; but it is at the same time rich and beautiful, and a graceful bird in its form. Some idea of it may be formed from the figure on the plate—PARROTS.

Tricoloured Macaw (M. tricolor). The name of this species is by no means happy, inasmuch as several of the other macaws, indeed most of them, have three colours in the plumage, and generally colours which contrast strongly with each other. The present one

has the top of the head and the lower parts of the cheeks red, the hind neck yellow, the coverts of the wings brownish red, and the quills blue. The tail-feathers are bright crimson, bordered with blue and tipped with the same, except the two middle ones, which are bright blue and tipped with crimson. The naked skin on the cheeks is marked with small lines of reddish feathers, and the under part is clouded with the same. This species is about twenty inches in length, and occurs in various parts of tropical America, but its manners are little known.

Illiger's Macaw (*M. Illigeri*), is a Brazilian species, measuring about eighteen inches in length, and very different from any of the rest in the markings of its plumage. The forehead is orange-red, and the remainder of the head and the neck greenish blue; the larger quills and the tips of the tail-feathers are bright blue; the remaining part of the tail-feathers are purplish red on the upper part, and yellowish on the under: the general plumage is green, and the bill and feet are blackish.

There are many other species of macaws to be met with in collections; and probably there may exist in the forests of central America many species which have not been hitherto observed. There is, however, so much similarity among all the macaws, excepting in size and colour, that when the manners of one are known, a tolerable index is obtained to the manners of the whole. In the country which they inhabit, they are exceedingly numerous and highly characteristic; and as they are very voracious, and feed almost exclusively upon fruits of some kind or other, their numbers are sufficient evidence of the vast abundance in which wild fruits of some kind or other are found in those forests at every season of the year. They do not range so far in latitude as some of the lighter species with tails somewhat differently formed, to which we shall afterwards have occasion to allude; but still they range from the upper part of the valley of La Plata to Mexico, and from the eastern extremities of Brazil to the slopes of the Andes. The centre of their territory may be regarded as being the river Amazon, the line of which lies near the Equator, and whose valley slopes so gradually toward the sea, that the effect of the trade winds, and of the air which those winds put in motion, is felt almost to the base of the mountains, or at least to that mighty forest which lies immediately to the east of them, and probably contains a greater abundance and luxuriance of wild fruit-trees than any other forest on the surface of the globe. The great rivers which empty their waters into the Amazon, the chief of which come from the south, contain in their valleys immense forests of a similar character; so that no place could be mentioned where the food of birds constructed like the macaws exists in such plenty. The birds are well fitted for the part which is thus assigned them. They are by much the largest of the parrot family, and they are more completely armed at all points than any of the rest. It is true they are not good walkers; but with them walking is not necessary. Their food is found on the trees; and when it falls to the ground, they abandon it to the small mammalia which gather their food beneath the shade of the trees. Their wings are, in all the species, powerful instruments, and firmly and neatly formed for flight. They are not proportionally so long as the wings of those birds which have to take extended migrations, or to chase their food on the wing; but

they are what one would call cleaver wings, equally fitted for forward flight, for turning, and for ascent and descent. In those movements, especially the up and down ones, the powerful tail is of great use to them. Their feet are also of first-rate character as climbing feet; and their bills are of stronger make and firmer consistency than those of any others of the race. Taking them altogether in their adaptations to wild nature, they unquestionably stand foremost in the parrot family; though many of the others are far more docile and engaging in their manners, and on that account better fitted for being kept as ornaments. It is in wild nature, however, that we must look for the proper characteristics of every bird or other animal; and perhaps there is not in the whole living creation a finer specimen of adaptation than we meet with in these birds, nor is there a country which presents so extensive and inviting a field to the student of Nature as that which the macaws inhabit, and make gay with their colours, and keep in incessant din with the loudness and harshness of their cries.

MACAW PARAKEETS. There is some little uncertainty in the application of the word parakeet. Its general signification may be considered as a diminutive of the word parrot, and the parakeet generally has the tail longer than the parrot, and pointed, or wedge-shaped, or with the middle feathers very much produced. The birds brought together under this name are of a mixed character, and do not, like the macaws, form a distinct section, occupying a particular locality. In one or other of their species they are found both in the eastern and western continent; though those of the west may perhaps be considered as resembling the macaws much more than those of the east do. Like the macaws, the parakeets are found only in the most fertile places of the world, though they have a much greater range than the macaws. In America, for example, there is one at least which ranges as far to the north as the southern part of the United States; while in South America there are others which reach as far southward as the Strait of Magellan. In the eastern continent we do not find them so far to the north; but they extend to the southern extremity of the land, and are chiefly dispersed over the islands. Even in this hemisphere, however, they do not inhabit such high latitudes as in America; but they do so simply because there are no such high latitudes on land for them to inhabit.

None of these birds have the cheeks so completely bare of feathers as the macaws; but the American ones have them more naked than those of the east; and they farther approach the macaws in character by being less susceptible of education than the eastern parakeets, or parakeets properly so called. We shall mention a few of the species without much reference to the subordinate sections into which it has been attempted to divide them; because those sections are by no means clear or satisfactory.

Psittacara is the name usually given to this genus or sub-division, and it is nothing more than a compound of the generic names of parrot and macaw.

Noble Parrot Macaw (*P. nobilis*), is an American species, and the one which resembles the macaws most nearly in its plumage. It is, however, smaller than the greater part of the macaws, and it is a bird which, taken altogether, has a feebler and softer air. The feathers are not nearly so firm in their texture; and on the under part they have the appearance of down and not of scales; the upper mandible too is

not nearly so strong nor so much hooked; and the head is not so thick and firm, because the muscles that work the jaws are not so large. This species has been called the Guiana parrot; but this appellation is an incorrect one, inasmuch as it is found pretty generally distributed over the warmer parts of the American continent, and reaches farther to the south than most, or perhaps than any of the macaws. It is but a small bird, being only twelve inches in total length, of which the tail occupies a full half; the upper mandible and naked space round the eye are yellowish white; the lower mandible is grey; the head as far as over the eyes light blue, the feathers bearing some resemblance to hairs. The whole of the upper part and under part are tolerably bright green, with the exception of the turn of the wing, the under wing-coverts, and the under side of the tail-feathers, where the wings are bright vermilion-red, and the tail yellow with a slight tinge of green. It is understood that this species lives on the kernels of hard fruits, which it is very dexterous in breaking, though its bill is upon the whole less powerful in proportion to its size than the bills of the macaws. Those who are fond of tracing gradations from one race of animals to another, are generally disposed to class this bird as something intermediate between the macaws and the American parrots properly so called; but its bill and feet are differently constructed from those of the true parrots; and its air and expression, and also its docility, are totally different; while, on the other hand, its size is smaller, and its general shape more elegant. So far as is known of its manners it agrees with its expression, for it is a wild and clamorous bird in its native haunts, and not capable of articulating or of affording any sort of amusement in a state of captivity.

Patagonian Macaw-Parrot (P. Patagonus). This is the least tropical of the whole of the parrot race, being found in that country after which it is named, even down to its southern extremity. It is olive-brown on the upper part with exception of the rump, which is yellow; the forehead is blackish, the head brown, the cheeks and wing-coverts olive; the rump, the upper tail-coverts, the sides of the belly, and the vent-feathers yellow; the quills brown with purple reflections; the tail-feathers olive brown, the breast brownish mottled with black; the middle of the belly reddish, and the bill and feet ash-colour; its length is eighteen inches. It will be seen from the description of the colours, that this parrot, which inhabits a colder latitude than the rest, though still a latitude which is tropical in its vegetation, has its colours much more broken than those species which live near the equator; and this is part of the character of a bird of temperate climates. In noticing the remaining species, which we shall do as briefly as possible, we shall omit the term macaw for the sake of brevity, though it is of course to be understood that all those which have the cheeks more or less naked partake a little of the macaw character. The greater number of the American ones which remain to be noticed are small birds in comparison.

Golden-crested Parakeet (P. auricapillus). This is a Brazilian species, and one of the largest of the long-tailed ones, being about ten inches in length. The general plumage is green, the forehead red, and the top of the head yellow; the quills are blue on their external surfaces, and so are the principal coverts; but the under sides of the wings are

purple-red; the tail-feathers are greenish yellow at their bases, and blue in the greater part of their length; the throat and breast are yellowish mottled with purple; and the belly, the vent-feathers, and the rump are purple; the bill and feet are ash-colour.

The scaly Parakeet (P. squamosus), is another Brazilian species, smaller than the last-mentioned, being only eight inches in length. It is green on the upper part, with blue reflections on the quills of the wings, and with the under sides yellow; but the under coverts of the wing, and also the bastard wing are red; the rump and belly, and also half-collar on the neck are bluish, with orange margins to the feathers, which makes them appear distinct from each other, as if they were scales—whence the name; but the name is an inaccurate one, inasmuch as the feathers have nothing of a scaly character.

Party-coloured Parakeet (P. versicolor). This species is described as being found in the forests of Guiana. It is about nine inches in length, and gets its name from the varied colours of the throat; the head is brown, the upper part green; the forehead and collar blue; the primary quills blue externally, with green reflections, and the bastard wing red; the ear-coverts are grey; the neck, throat, and breast are variable brown, with the margins of the feathers lighter; the rump and tail-feathers are purple-brown, the flanks green, and the bill and feet blackish.

There are several other species of parakeets in South America with the cheeks more or less naked, and the tails, generally speaking, broad and spreading for about half their length, and wedge-shaped for the other half. The feathers being, generally speaking, twelve in number, the middle ones always the longest and of equal length with each other, and the point of each feather standing separate from each other when the tail is spread. The tail with which we are familiar in Europe, bearing the most resemblance to this, is that of the magpies; and though these birds are very different in their habits, and also in their food, from the magpies, and are zygodactylic, whereas the magpies are not, they resemble each other in many of their attitudes and also in their styles of flight. Being smaller birds than the macaws, and more habitually on the wing, they are found in more open places; in consequence of this they are more destructive to plantations than some of the larger ones are. In tropical America they are of course tree birds, but some of them frequent districts in which trees are few, and they nestle in the holes of rocks. This is the case with the Patagonian species, which is a hardy bird, and inhabits the mountains to a considerable elevation. The flocks of them are sometimes immense; and, as at the time when they flock they are very bold and daring, the inhabitants slaughter them in great numbers as plunderers of their gardens and fields. It is unnecessary to enter at length into the details of the species, because it would be little else than a repetition of mere colours. There is, however, one species which it would be injustice to pass over without notice, because it is the only one which is found in the temperate latitudes of the northern hemisphere. This species is,

The Carolina Parakeet (P. Carolinensis). The name Carolina is very improperly applied to this bird, because, even when it was most plentiful in North America, Carolina was not the chief place of its residence. On the Atlantic shores, according to

Wilson, it seldom occurred to the northward of Maryland, whereas in the great central valley of the Mississippi, it ranged as far northward as the shores of Lake Michigan, which is actually on the Canadian side of the water-shed. Wilson describes it as occurring in no scanty numbers, and as being resident during the whole year, and capable of standing the severest weather. He distinctly mentions having seen them near the banks of the Ohio, in the month of February, "flying about like pigeons and in full cry." Audubon says, that they are not so numerous in the north-western states now as Wilson describes them to have been in his time; and that, though there are a few in the country north of the Ohio, they do not occur in numbers until the confluence of that river with the Mississippi is arrived at. Some have attempted to account for this as a fact, by the cutting down of great numbers of the old and decayed trees in which the birds built their nests. There are still, however, a sufficient number of such trees in the north-west territory for accommodating any number of these parakeets; and therefore, if the numbers have fallen off, and the birds also withdrawn to more southerly habitations, the cause must be sought somewhere else. We know that the Americans have exterminated the wild turkeys from very many parts of the United States; but they have done so in inconsiderate zeal for *pot-fouling*, a purpose for which the parakeets of North America are certainly not the very best adapted.

If we take the average circumstances which have occurred in other countries, and have influenced the appearance or the disappearance of races of birds, we can really see no circumstance in North America which could render the north-western part of the United States a less comfortable country for those parakeets at the present time than it was thirty years ago. The population is not certainly yet so dense as to be any annoyance to them, and they cannot be driven southward by the greater severity of the seasons, for clearing and cultivation improve the climate in all other parts of the world, and it would be strange indeed if they produced an opposite effect in America. We have of course no disposition to question the authority of Audubon, who, we dare say, repeated very faithfully what was told him; but the fact is so much at variance with the physical circumstances, that it would require some sort of explanation. It is true that, regarding them as great plunderers of orchards, the American settlers have been very zealous in the destruction of these birds; and the birds, like the rest of this division of the parrot family, are so fearless that one may continue firing away upon the flock until immense numbers of them are destroyed, without those which remain unshot being frightened away. It should seem too that the fact of firing on these birds is more cruel than wise, just as the fact of firing upon birds sometimes is in this country. These parakeets may sometimes do a little mischief in the gardens, though the produce of the gardens is pretty nearly over by the time that they begin to flock. Their principal resort are the fields, and their favourite food is the seed of the cockle-burr (*Xanthium strumarium*), which is one of the greatest pests that annoy cultivators, in the great western valley of the United States. It is highly probable that the comparative rarity of this plant on the poorer soil toward the Atlantic may be one of the causes why the birds do not find their way so far to the

northward on that side of Alleghany Mountains. On the Ohio side of the mountains the bottoms are far richer. The burr alluded to is a composite plant, producing, like the whole of that order, an immense number of seeds; and thus tending to spread itself over every piece of ground which man has cleared of timber or recovered from being a swamp. In a wide country like America, human labour can but ill contend with the progress of a plant of this description; and the inhabitants of Canada, to the northward of Lake Ontario, can tell how terrible the infliction is where one of these composite plants comes in full force to take possession of a district. According to Wilson's account, and he is still the best, though not the most recent authority, these parakeets appear to have especial charge of the cockle-burr, and they visit the fields in tens of thousands, apparently for the express purpose of destroying its seeds. The plant and the bird, taken in conjunction, appear therefore to be worthy of a little more philosophical attention than they have hitherto met with. It is not a little remarkable that in the temperate latitudes of America the fields have a great tendency to be overrun by composite plants of some description or other. The rich parts of the Pampas, to the south-westward of Buenos Ayres, are at some seasons of the year completely overrun with thistles; and it is not a little remarkable that the portion of North America which has the greatest tendency to be overrun with these burrs is very nearly in the same latitude north as the Pampas is south. Nor is it less remarkable that the Patagonian parakeet ranges over the Pampas at certain seasons of the year, much in the same manner as the Carolina parakeet ranges over the plains on the banks of the Mississippi and its branches.

The circumstances which we have now stated will show that this parakeet is one of peculiar interest, and therefore we shall venture to quote Wilson's description of it, with one or two of his highly interesting anecdotes.—"The Carolina or Illinois parrot (for it has been described under both these appellations)," says Wilson, "is thirteen inches long and twenty-one in extent; forehead and cheeks orange-red; beyond this, for an inch and a half, down and round the neck, a rich and pure yellow; shoulder and bend of the wing also edged with rich orange-red; the general colour of the rest of the plumage is bright yellowish silky green, with light-blue reflections, lighted and most diluted with yellow below; greater wing-coverts and roots of the primaries deep dusky purple, almost black, exterior ones bluish green; tail long, cuneiform, consisting of twelve feathers, the exterior one only half the length, the others increasing to the middle ones, which are streaked along the middle with light blue; shafts of all the feathers, and of most part of the green plumage, black; knees and vent orange yellow; feet a pale whitish flesh-colour; claws black; bill white, or slightly tinged with pale cream; iris of the eye hazel; round the eye is a small space without feathers, covered with a whitish skin; nostrils placed in an elevated membrane at the base of the bill, and covered with feathers; chin wholly bare of feathers, but concealed by those descending on each side; from each side of the palate hangs a lobe or skin of a blackish colour; tongue thick and fleshy; inside of the upper mandible, near the point, grooved exactly like a file, that it may hold with more security. The female differs very little in her colours and markings

from the male. After examining numerous specimens, the following appear to be the principal differences:—The yellow on the neck of the female does not descend quite so far; the interior vanes of the primaries are brownish instead of black, and the orange-red on the head and edges of the wing is considerably narrower; in other respects the colours and markings are nearly the same. The young birds of the preceding year, of both sexes, are generally destitute of the yellow on the head and neck until about the beginning or middle of March, having these parts wholly green, except the front and cheeks, which are orange-red in them as in the full-grown birds. Towards the middle of March the yellow begins to appear, in detached feathers, interspersed among the green, varying in different individuals. In some, which I have killed about the last of that month, only a few green feathers remained among the yellow, and these were fast assuming the yellow tint; for the colour changes without change of plumage."

Wilson was not able to ascertain, by personal inspection, the exact position of the nests of these birds, or the length of time which the female sits; but he made rather an interesting experiment on the education of one. The specimen which he used for this purpose was but slightly wounded in the wing, and readily ate the seeds of cockle-burs almost as soon as it was taken. In travelling through the woods, he bound it up in a handkerchief, and carried it in his pocket, but loosed and fed it always when he rested. He must, however, be allowed to tell part of his own story:—"In recommitting it to 'durance vile' we generally had a quarrel, during which it frequently paid me in kind for the wound I had inflicted, and for depriving it of liberty, by cutting and almost disabling several of my fingers with its sharp and powerful bill. The path through the wilderness between Nashville and Natchez is often bad beyond description. There are dangerous creeks to swim, miles of morass to struggle through, rendered almost as gloomy as night by a prodigious growth of timber, and an underwood of canes and other evergreens, while the descent into these sluggish streams is often ten or fifteen feet perpendicular into a bed of clay. In some of the worst of these places, where I had, as it were, to fight my way through, the parakeet frequently escaped from my pocket, obliging me to dismount and pursue it through the worst of the morass before I could regain it. On these occasions I was several times tempted to abandon it, but I persisted in bringing it along. When at night I encamped in the woods, I placed it on the baggage beside me, where it usually sat, with great composure, dozing and grazing at the fire, till morning. In this manner I carried it upwards of a thousand miles in my pocket, where it was exposed all day to the joking of the horse, but regularly liberated at meal-times and in the evening." On arriving at the house of a friend, Wilson placed it in a cage under the portico, and its call-note speedily attracted a number of its fellows. One of these was wounded, and placed beside the former, and the attachment which they showed to each other was truly wonderful in birds; and when the last-caught one died, the other appeared quite disconsolate for some days. We must again refer to Wilson for the catastrophe of this most interesting tale of animal history:—"On reaching New Orleans," says he, "I placed a looking-glass beside the place where she usually sat, and the

instant she perceived her image all her former fondness seemed to return, so that she could scarcely absent herself from it a moment. It was evident that she was completely deceived. Always when evening drew on, and often during the day, she laid her head close to the image in the glass, and began to doze with great composure and satisfaction. In this short space she had learned to know her name—to answer and come when called on—to climb up my clothes—sit on my shoulders—and eat from my mouth. I took her with me to sea, determined to persevere in her education; but, destined to another fate, poor Poll, one morning, about daybreak, wrought her way through the cage while I was asleep, instantly flew overboard, and perished in the Gulf of Mexico."

There is still another species of parakeet, which is worthy of notice, as being the only one with a portion of the cheeks naked, which occurs in any part of the eastern continent or its islands. This is

The Solstitial Parakeet (P. solstitialis). It is a native of Africa, especially of those fertile regions which lie on the west coast between the equator and the fifteenth degree of south latitude, but it has been transported to Brazil, and is naturalised there in the wild state. It is not a large species, being only about eleven inches in length. The upper part is yellow, with reddish borders to the feathers; and the top of the head, the front, the cheeks, the fore neck, and the under parts of the body, are orange; the primary quills are margined with green, and have blue tips; the two middle feathers of the tail are green, with blue tips, and the lateral ones are blue, with grey borders; the bill and the feet are grey. The female has the plumage in great part yellow; but the forehead, the sides of the head, and a portion of the under part, are reddish orange; the rump, the upper tail-coverts, and the feathered part of the legs, are brown mottled with green and yellow; and the quills and tail-feathers are green, with blue borders. The young birds have the rump and the belly red; the head, the neck, and the breast, mottled with reddish; and the upper coverts of the tail green. It is necessary to attend to these distinctions of sex and age, because the three have sometimes been described as three distinct species.

We shall now proceed to the PARAKEETS properly so called, which have no naked skin round the eyes, and which, generally speaking, have the two middle feathers of the tail much longer than the others, on account of which latter circumstance they are sometimes called "arrow-tailed" birds. They are all natives of the eastern continent; their bodies, generally speaking, partake more of the parrot form than the American ones do. Some of them are exceedingly beautiful in their plumage; the greater part are gentle and docile in their manners; and some at least can be taught to articulate a considerable number of words. The species are exceedingly numerous; and, therefore, all that we can possibly do is to enumerate a few of them as specimens of the whole; and we may remark in passing, that, as they trench on the confines of some of the other sections of the family, it is extremely difficult to give anything like accuracy to a minute and circumstantial list of them.

If we are to consider them as a genus, the following may be said to be their leading characters: the bill thickish, but not so large in proportion as in the macaws; the upper mandible widened at the base,

rounded in the culmen, and the lower one closing upon it in some of the species at more than a right angle; the cutting edges of both mandibles are strongly toothed or margined, so that the bill can retain a substance with great firmness; the tongue is thick and fleshy, smooth on the surface, and without any appendages; wings are of medium length, and the first, second, and third quills are nearly equal; the exterior webs of these are broad at the middle part; but they become very short toward the tip, thereby bringing the three shafts close to each other, and giving a pointed appearance and also great firmness to the wing; the tail is very wedge-shaped, the lateral feathers being short as compared with those nearer the middle, and the two middle ones very long and rounded at the tips. They are birds which have been admired from the remotest antiquity for the gracefulness of their forms, the beauty of their plumage, and, if the expression may be allowed, their faculty of speech, though like all the rest of articulating animals, they must stand acquitted of understanding a single word that they utter. No doubt they sometimes suit the word to the occasion, at least apparently, though it is purely accidental on their part. They distinguish places and persons, however, and discriminate between those who are kind to them and those who are not; but these are mere animal propensities, found in many animals, and probably existing in all if we could find them out; and therefore they have no more to do with anything like mental reasoning and judgment than is possessed by the mere fact of seeing with an eye, hearing with an ear, resorting to the proper kind of food, or keeping out of the way of danger.

Alexander's Ring-Parakeet (P. Alexanderi). This is a very beautiful bird, and it bears a royal name, for it is called after no less a personage than the mighty Macedonian himself, who, though he conquered, always conquered with magnanimity, and showed a desire to promote the welfare of man and the kindly treatment of the lower animals: his positive injunctions to his army, that they should injure none of the peacocks or other beautiful birds of India, is a proof that the lessons of Aristotle were not thrown away upon him; and it deserves to be known more generally than it really is, that Alexander did not lose his life by the excess of a banquet at Babylon, as the vulgar story has it; but that he lost it in his zeal to obtain a proper drainage of the neighbouring marshes, in order to improve the salubrity of the city, and the navigation of the Euphrates.

This beautiful species is about twenty inches in length, but twelve or fourteen of that are occupied by the tail. The general colour of the upper parts is green, varying in different shades so as to show off the individual feathers; the turns of the wings are bright red, which extends as far as the bastard wing, forming a large and beautiful spot in the middle of the green; the throat in front has a deep black collar which narrows toward the nape, and under it there is a collar of brilliant red, advancing forward nearly to the throat on each side, but not meeting; the bill also is red; the under sides of the wing and tail-feathers, and the tips of the latter, are yellow, and the under part of the bird generally green, but of a much lighter tint than the upper parts. The shape and action of the bird are very graceful, its manners are gentle, it acquires great docility, and articulates well. It is therefore a favourite bird, and there is perhaps not one more so in the parrot family; because,

though some of the snort-tailed parrots perhaps speak better, none of them is nearly so handsome or so gentle in disposition.

At this distance of time, it is not easy to say which of the Indian parakeets was first introduced into the western world, or whether several species may not have been brought. It is well ascertained that, long before Alexander's invasion, the Egyptians carried on a considerable commerce with India; and as the Indian birds and other animals appear to have always been great favourites in the western world, it is by no means improbable that parrots were introduced by the way of Egypt even before the invasion of India by Sesostris. Though much nearer in geographical situation, the parrots of Asia do not appear to have been introduced into Europe till some time after the commencement of the Christian era; and we accordingly do not find any allusions to them in the classical writers, though there are such allusions to the Indian ones. It is worthy of remark, that those handsome and splendid birds have preserved their interest for a period of between two thousand and three thousand years, so that they continue to be sought after with as much avidity as ever.

There are at least five other parakeets of continental India, having the two middle feathers of the tail much longer than any of the lateral ones. Their manners, however, so far as they are known in a state of nature, are nearly the same, and the chief differences between them are those of size and colour; hence we must content ourselves with a mere list of them.

Pondicherry Parakeet (P. Pondicerianus). As its local name implies, this species is found on the Coromandel east of southern India. It is about fourteen inches in length; the upper parts are deep green; the quills bordered with yellow on the outer webs, and with blue on the inner; the larger coverts of the wings have blue tips, and the smaller ones yellow; the top of the head and the cheeks are pale violet or lilac; there are large black mustachies descending from the angles of the gape, and a band of black over the eyes; the middle tail-feathers are blue, and the lateral ones green with blue tips; the throat, fore neck, and breast are bright rose-colour; the under parts are dull green; the bill red at the base, and ash-coloured at the tip, and the feet grey.

Bengal Parakeet (P. Bengalensis). This species is rather smaller than the former, being about thirteen inches in length; the upper parts are yellowish green, the forehead and upper part of the face red; the cheeks and hind head violet, the collar on the neck black, and the hind neck and scapulars bluish green; the bastard wing red, the middle tail-feathers violet-blue with pale yellow tips, the lateral ones green tipped with bright yellow, the under parts of the body yellowish, the upper mandible whitish, the lower brown, and the feet black.

Yellow-ringed Parakeet, (P. annulatus), is rather larger than the former, being fifteen inches in length. It is brilliant green on the upper part, and yellowish green on the under. The head is blue; the forehead, cheeks, and throat brownish, marked with a very distinct yellow collar. The middle tail-feathers are blue, with yellow tips; the bill is yellow, and the feet grey. The female has the head grey mottled with paler spots. These birds are found in various parts of India.

Yellow-shouldered Parakeet, (P. xanthonotus), is

green on the upper part, with the head, neck, and wing-coverts pale greenish blue. The primary quills have black tips. The under parts are of a very clear pale green. The smaller coverts of the wings are yellow; and there is a spot of the same colour on each shoulder. A circle round the eye is rose-colour, the bill red, and the feet black. It is very doubtful whether this species occurs on any part of continental Asia; for the specimens of it which have reached Europe have been brought from the oriental isles.

Double-collared Parakeet (P. bitorquatus). There is some doubt about this species also; and some of the authorities speak of it as a native of the Mauritius. But birds and other productions of India and the Indian islands have been so often brought from the isles on the east of Africa, or the Cape of Good Hope, as native productions of these places, that it is very difficult to discover the truth in the case of some of the rarer ones, of which only a specimen or two have been seen. All the upper plumage of this species is deep green; and the throat is black, surrounded by a double collar, the upper portion of which is bright blue, and the under one brilliant rose-colour. The under sides of the wings and tail are olive green, the belly olive brown, the bill red above and brown below, and the feet black. The length is about thirteen inches.

Ring Parakeet (P. torquatus). This is another species of which the geographical distribution is not completely decided. Some of the authorities say that it is found in western Africa, as well as in India; but, if it occurs in the former country, it is an anomaly, as all the others which have the middle feathers of the tail much produced belong to the south-east of Asia, or to the islands still to the south and east. The name, ringed, is also inapplicable; because all the parakeets, with long middle feathers in the tail, have more or less of a collar on the neck. The plumage of this one is pale green, with the throat and collar black, bordered with rose-colour on the hind neck; and there is a black streak from the gape to the eye. The quills are deep green on the upper sides, and greyish on the under. The middle tail-feathers are bluish green, and lateral ones yellowish green on the upper sides, but the whole are yellow on the under. The flanks are also yellow, and the bill is red, except the tip of the lower mandible, which is black. The length is about fifteen inches. The females and the young are entirely green, or green with a few partial mottlings of yellow.

Some of the parakeets of this form which occur in the eastern islands and in New Holland differ a little in their general appearance and expression from the Indian ones. Their bills are, generally speaking, more slender, and also their bodies; the middle tail-feathers more produced, and the whole expression softer. We can afford room for only a single species of each, as a specimen.

Molucco Parakeet (P. Moluccensis). This light and beautiful species, which is one of the most delicate in appearance of the whole race, is found in the Molucco or Spice Islands, and several adjoining parts of the Oriental Archipelago, though some recent copyists have described it as being a native of Malacca, and so being a town-bred bird, instead of a country one. This would be a curious new fact in natural history; for we are not aware of any one species of bird having its primary origin in a town;

NAT. HIST.—VOL. III.

and there is very good reason why there should not, because birds were made before towns were built. A cap on the top of the head of this one is shining green. The hind head and neck are violet rose-colour, with a curve of black descending from the base of the lower mandible and turning backward; the back, throat, and breast bright green; the wing-coverts green, with yellowish margins to the feathers; the quills blue at their bases, and blackish toward their extremities; the long tail feathers bright violet blue, the lateral ones yellowish green; the flanks yellowish; the upper mandible red, and the under one of yellowish brown. The length of this species is about seventeen inches, of which the tail occupies considerably more than half. It is a light bird for its lateral dimensions; and its wings are long and powerful for its weight, so that it floats in the air like a meteor. A bird so capable of ranging about is not likely to be confined to any very narrow locality; but probably extends from Sumatra on the west to New Guinea on the east. This bird affords a striking instance of the mischief which is done to the geography of animals by the absurd custom of naming an animal after the particular locality from which the first specimen was obtained, while the animal itself has a much wider range. If we take the Indian Archipelago as extending from Sumatra to New Guinea, the Moluccos are only a few little specks in it; and, though the Dutch are said to have been very successful in extirpating each of the more valuable species from all the islands except one, the parakeets have too much power of themselves in the air for suffering even a "flying Dutchman" to extirpate them from any one island they choose to inhabit; and, therefore, it is highly probable that every species is distributed over a pretty wide extent; and not only so, but it is highly probable that these birds as well as the other forest birds of the same parts of the world, shift their localities with the monsoons.

Swainson's Parakeet (P. Swainsonii). This is a very handsome species, a native of New Holland; and it is somewhat different in character from the species of India and the Indian Islands. The most obvious difference is in the tail, of which the two middle feathers are not so much longer than the rest as in the others; while the lateral feathers of the tail have much more tendency to spread. From this structure of the tail, in which the bird makes a slight approach to the broad-tailed parrots of Australia, we would naturally conclude that it alights more frequently on the ground than those of India and the Isles. This is further confirmed by the character of the feet, which have the tarsi longer, and the articulations of the toes with less lateral motion, than those birds which are exclusively perchers and climbers. We are, however, in perfect ignorance as to the habits of the bird; nor do we know exactly to what particular parts of the East it extends. Australia is named as its residence; and certainly the expansile tail and the firm feet would suit it for subsisting in that country, where, at certain seasons of the year at least, even a parakeet must in part seek its food in those farinaceous roots, the tops of which are left leafless above the barren surface during the long and severe drought to which the country is subject. This species is about sixteen inches in length, of which the tail measures nine. The upper mandible is red on the sides, and yellowish in the culmen; and the lower

C C

mandible is brownish. The front is golden yellow, extending upward to nearly the middle of the head. From the gape, over the eyes, and down to the nape, is bright green, which is also the general colour of the body, both on the upper part and the under. The chin, the lower parts of the cheeks, the throat, fore-neck, and sides of the neck, are rich yellow, passing gradually into a collar of dull red. A small portion of the hind head and the outer margins of the quills are blue. The tail differs from the tails of the others, in the form and colouring of the feathers, as well as in the general shape. The whole is green on the upper part; and the two middle feathers are very stout and broad, and only two inches longer than the rest; whereas the Indian ones have those feathers four inches longer, and the islander which we have noticed has them at least six. The tail is also more powerfully fortified by coverts, especially on the upper side, than in the Indian ones, and more especially than those of the isles, which have the base of the tail but little fortified.

There is no doubt that, if the manners of this parakeet could be ascertained by observation, it would be found that its structure agrees with the physical character of its native country. We have, indeed, remarkable instances of coincidences between country and inhabitant, in the parakeets of the three localities. The Oriental Archipelago is to a great extent a perennial garden; New Holland is for great part of the year parched with drought, and it is probable that very large tracts of it are alternately stagnant water and sun-baked mud, impregnated with salt, and incapable of producing any vegetable; and India, taking it in its general character, is intermediate between the two. Now, the parakeet of the isles is all for the wing, and the tail is so feeble that it can serve little purpose save that of a streamer; the Australian one has this organ vigorous, capable of spreading to a considerable extent in the air, and fortified for acting against the air with considerable effect; and the Indian one has an intermediate character. It is to be regretted that there are no data for working out in a satisfactory manner those relations between bird and country; because the birds, of tropical countries especially, are so numerous and beautiful, that if we could but apply them they would form a most delightful index to the general natural history of those countries.

There still remain to be noticed a vast number of parakeets, perhaps not fewer than sixty or seventy species, well made out; and this is a muster-roll which no ordinary reader could be expected to get through. These many writers characterise as the true parakeets. Like the last-mentioned ones, they have the cheeks completely feathered; but their tails are differently constructed. They are, generally speaking, long; but the two middle feathers are not greatly produced beyond the others, neither do they differ from the others in their general structure. The tails are, generally speaking, acutely wedge-shaped; but then, as we proceed from the lateral feathers toward the central ones, the excess in length of each feather beyond the one immediately external of it is almost the same throughout the whole.

There is one circumstance which has tended to render this sub-division of the parakeet so exceedingly confused, that one can with extreme difficulty grope one's way through it; and that is the fact of having

placed every member of the parrot family, with a long wedge-shaped tail and feathers on the cheeks, and being rather diminutive in size, within this sub-division. Accordingly we have these parakeets in all parts of the world, though probably many of them ought to rank with some of the other sub-families, or at all events to be formed into distinct genera or sub-genera, in terms of their own specific organisation and habits, and without reference to any gratuitous hypotheses, whether *quinary*, or any, other more aberrant from common sense as possible. The characters which we have mentioned, namely, the feathered cheeks, and the long tail greatly but uniformly wedge-shaped, are the only characters which apply to the whole of these, and distinguish them from the others; and they are but scanty foundations upon which to build anything like a natural history of birds so exceedingly numerous, and differing so much from each other in various parts of their individual characters. There is another disadvantage attending the matter, and that is, our comparative ignorance of the habits of these birds. From their structure we are led to conclude that they are, generally speaking, eaters of fruit; but in what they differ from the rest of the family in this respect, and in what particular part of the forest or of the field they have their natural labour assigned to them, we are perfectly ignorant. All that we can do under such circumstances, therefore, is to mention one or two of the species as specimens of the whole, and we shall take them from different countries, remarking, in passing, that by far the greater number of them appear to be natives of Australia, though they Africa are also found in India, in the Oriental Islands, and its islands, in the tropical parts of the western continent and also in its inter-tropical appendages.

Bordered-wing Parakeet (P. marginatus), is a native of India. Its general plumage is green, with a blue band on the top of the head, and blue on the fore part of the body, the feathers externally bordered with yellow. The wing-coverts next the body are blue with yellow borders, the others are green marked with yellow. The quills are brown, marked out with borders of the same colour a good deal paler; and the tail-feathers are green above and yellow below. The bill is red and the feet black.

The species of those wedge-tailed parakeets occurring in the south-eastern parts of Continental Asia are few, compared with those which occur in the eastern Archipelago, and these latter again are few as compared with the Australian ones. Some of them in both countries are very handsome birds.

Flat-tailed Parakeet (P. platyrus), is one of the species of the Oriental Islands. It is greenish ash-colour on the upper part, and brilliant green on the head and neck, surmounted by a coronet of bluish ash, with a large red spot in front of it, and it has a half collar of orange on the neck. The lesser coverts of the wings are grey, and quills green. The intermediate feathers of the tail are green, and have a portion of the shafts without barbs, and much longer than the other feathers. The under part is yellowish green, and the bill and feet brown. The length is about eleven inches.

Lichtenstein's Parakeet (P. Lichtensteinii), is an Indian species of rather portly dimensions, being seventeen inches in length. Its general plumage is green, with the top of the head blue, and the hind part of the neck and belly black. The flanks and tips of the quills are yellow, the bill red, and the feet black.

Latham's Parakeet (*P. Lathamii*), is an Australian bird, only eight inches in length. The general plumage is shining green varied with bluish on the head. A small space round the eye, the bastard wing, and the upper coverts of the tail, are red, with bluish borders to the feathers, the under tail coverts are yellow. The greater wing coverts are blue, some of them bordered with white. The under coverts are yellow, the bill and feet are brown.

Many-coloured Parakeet (*P. multicolor*), is also an Australian species, about eleven inches in length. The upper parts are green, passing into olive on the back. The front is yellow, the middle of the cheeks red, the shoulders orange, and the bastard wing and under coverts of the wings blue. The quills are black, with blue at their outer margins. The tail feathers green, variegated with bright blue and black, the belly is reddish yellow, and the bill and feet ash-colour.

New Zealand Parakeet (*P. Nova Zelandiae*), is green on the upper part, and the same on the under, but a shade lighter. The crown of the head, the eye-spots and the sides of the rump are red. The quills are blue on their external edges. The length about nine or ten inches.

Such are a few of the wedge-tailed parakeets by way of specimens; and though we were to go through the whole of the long list, we should be able to give but little information further than an enumeration of mere varieties of colour. From the structure of their wings and tail, and the comparative lightness yet firmness of their bodies, we have every reason to believe that these are birds which act their part in nature with no inconsiderable energy. In point of disposition they appear to be intermediate between the macaw parakeets, and that subdivision of the eastern parakeets which have the produced feathers in the tail; being less wild and fierce than the former, and less gentle than the latter. They are not birds of much resource, neither are they capable of much education. We are but little acquainted with the use of them in wild nature, but from their numbers and their general distribution, we must presume that their use is considerable.

PARROTS.—The parrots, properly so called, are in some respects the most interesting birds of the whole family. They are by no means the handsomest, either in their forms or in the colours of their plumage. They are, however, the most dexterous climbers, and some of them at least are the most susceptible of being taught to articulate words. The general characters which distinguish them from the rest of the family are but few in number, but they are well marked and easily observed. They have the tail short and squared over at the extremity; the bill very stout, and greatly hooked in the upper mandible; the face entirely covered with feathers, and the body thick and strong, and very muscular. Their tarsi are short but stout, and they have great action with the toes as well as with the bill. There is much oblique motion at the articulation of the toes, so that the foot can be turned almost directly outwards, and for this reason they are but ill adapted for walking on the ground, but their climbing is very dexterous and amusing. They are, properly speaking, tree birds, and use their wings much more in leaping from branch to branch, when the distance is too great for the stretch of their bill and feet, than they do in flying far distances; but they can fly when necessary, though not very rapidly, or very far upon a stretch. Among the branches of the

trees their wings are very clever, and ready to act in a comparatively small space. Their plumage is of an exceedingly firm texture and difficult to be ruffled; and the feathers of the neck are also firm and closely, individually rounded off at their extremities, and overlaying each other like distinct scales. This structure of plumage adapts them well for scrambling over among the leaves and twigs of trees, where they have their constant habitation, and find the greater part of their food. As is the case with the members of some others of the subdivisions, the parrots are but ill defined. The greater number of them are natives of tropical America, where the trees furnish them with an ample supply of food. There is one, however, which is a native of Africa, though there are some distinctions between it and the American ones, in the air of the body, the form of the bill and head, a certain portion of the face being naked, the general tint of the plumage, and several other characteristics. Of the species enumerated in many of the catalogues, some are doubtful, and others belong to different sections of the family. On this account and also in order to keep our notice within limits as moderate as possible, we shall advert only to two or three of the leading ones; and as most people are familiar with them, even they will not require much notice.

Common Grey Parrot (*P. erythacus*). This bird has but little to boast of the gaudiness of its plumage being clad in sober grey with the exception of the tail feathers which are red; but still it is the parrot *par excellence* with those who are fond of the loquacity of these birds after they have been taught to speak. The whole plumage is soft ashen-grey, approaching to smoke colour, with the exception of the tail which is red, and sometimes brownish, the belly which is whitish, and the tips of the quills which are blackish; the naked space around and in front of the eye is whitish, and appears to be covered with a scaly powder, which the bird is very fond of having disturbed by gentle scratching; the bill and feet are black or blackish, contrasting pretty strongly with the sober colour of the general plumage. This bird, however, differs from all the American ones, which ought perhaps to be considered as the typical parrots, and also from the greater number, if not the whole, of the short-tailed birds of the parrot family, which are found in the eastern countries, in not having the slightest trace of green, or indeed any tendency to green, in its plumage. Some specimens have part of the feathers brownish, and others have them inclining to red; but we believe that no instance has occurred in which any trace of green, of blue, or of yellow, has appeared upon them. If difference of appearance, difference of colour, difference in the shape of the body, and of the head and bill, are to be considered a sufficient ground of generic distinction; then it is clear that this bird ought not to be placed in the same genus with the green parrots of South America. It is a native of western Africa, where it inhabits the thick forests in the richer parts of the country, and is understood to subsist entirely on wild fruits. Its manners in a state of nature are but little known, as is the case with every bird of the tropical forests. It is understood, however, to nestle in the holes of decayed trees, and seek no materials for its nest except the powder into which the wood has been reduced by the progress of natural decay, or the ravages of the wood-devouring insects. We are not sure that this part of its economy has been much observed in the

wild state, even by the natives of those districts in which it abounds; but the nesting place, and materials which it has selected in confinement, afford a sort of proof that the dust of the decayed trees is the only substance on which the eggs are deposited. The bird is of very gentle disposition, easily tamed, and by no means impatient of captivity; and, like other birds which are not over excited in this state, it is sometimes bred. Buffon mentions a pair which for five years successively brought up their young in France; and preferred to every other place a cask partially filled with sawdust, which is as near an approximation to a tree which has been hollowed by the depredations of insects, and only a small portion of the exterior left sound, as can well be supposed. The eggs are described as being four in number, of a white colour, and about the size of those of a pigeon. One of the smallest-sized pigeons is indeed the European bird which is most nearly equal in bulk to the grey parrot.

The bill of this parrot, though differently formed from the bills of the American parrots, is an exceedingly powerful instrument. In the course of this work we have had occasion to remark again and again, that dark-coloured bills and claws are always the most firm and compact in their structure; and the strength of the grey parrot's bill is a practical proof of this. It is true that it is not quite so mischievous in the use of its bill as the green parrot; but the bill is a very efficient feeding instrument. The internal part of the hook of the upper mandible is very much roughened; and the ridges on the interior part of the palate, which occurs in all the nut-cracking parrots, are very firm, so that the bird can use the bill very readily in breaking the hardest shell of a fruit which the gape will admit within it. The foot, too, is capable of being used partially as a hand; and the bird can support itself upon one foot, while the bill and the other foot are jointly engaged in preparing the food. The bill indeed in this, and in several others of the species, partakes something of the nature of a pair of grinding jaws; for the food can be worked about in it, and held in its place by the tongue, until it is reduced to small portions. In doing this, however, there is a sort of deficiency in the absence of lips; so that when a parrot has to practise much of its peculiar kind of mastication, a considerable quantity of the food is lost, as the bird is quite incapable of picking up small fragments.

There are various accounts which appear to confirm the fact that this parrot is a very long-lived bird. Instances have been recorded of individuals which have lived in captivity to the age of fifty, of sixty, and even of a hundred years.

Le Vaillant gives an account of one which had lived thirty-two years with a gentleman, after having been previously forty-one years with his uncle, and it came into the possession of the latter as a full-grown bird, though of what age is not known. Altogether, however, it may be presumed that this specimen could not have been less than eighty years old at the time when it was seen by the naturalist. It had then lost its sight, and what may be called its memory; which latter, by the way, is a necessary result of the loss of sight. It was quite lethargic, speaking none and moving little; but it was respected on account of the length of its former services, and it was kept alive by biscuits soaked in Madeira wine. In the days of its prime it had been a prince of parrots, for it was capa-

ble of speaking many sentences, calling the servants, fetching a pair of slippers, and performing various other sayings and doings. In the sixtieth year of its confinement, its aptitude appeared to be in a great measure gone; for it not only never afterwards learned to articulate any new phrase, but very speedily forgot those of which it had previously learned the articulation, or jumbled them together in an incoherent manner, the same as is done by human beings when they have fallen into the dotage of old age. Till the sixty-fifth year it continued to moult regularly every year; but at that time the red feathers of the tail were shed, and replaced by yellowish-white feathers, after which the bird moulted no more, but continued in the same identical feathers to the end of its life.

It must not be supposed that this loss of capacity and memory on the part of this parrot was the slightest evidence of anything in the least resembling mind. On the contrary, they serve to reprove us for an inaccurate expression which we sometimes apply to human beings, when the display of the mind is rendered less conspicuous by the decay of the body. We are accustomed to say, in the case of such a person, "the mind is gone;" but nothing can be more erroneous. From its very nature the mind cannot undergo decay, and as the physical body is the instrument by means of which the mind takes cognisance of the physical world, it is quite evident that the mind must be controlled by its medium of perception; and that which we call a derangement of the mind, is, in reality, a derangement of the body, whether the derangement belongs to the class of madness or of dotage.

The grey or ash-coloured parrot not only learns to articulate clearly, and to whistle tunes with great accuracy both of tone and of time, but it is capable of playing a number of tricks which show considerable skill, though by no means equal to those performed by a well-trained dog. We can only afford room for a sentence or two more on the manners of this highly-interesting bird; and we shall give these in a quotation from Buffon. A grey parrot "being instructed on its voyage by an old sailor, had acquired his harsh hoarse voice so perfectly, that it was often mistaken for him. Though it was afterwards given to a young person, and no longer heard the voice, it never forgot the lessons of its old master, and it was exceedingly amusing to hear it pass from a soft pleasing voice to its old hoarse sea tone. This bird has not only a great facility in imitating the voice of man, but it also seems to have a wish to do so; and this wish is shown in its great attention, the efforts which it makes to repeat the sounds it hears, and its constant repetition of them; for it incessantly repeats any words which it has just learned, and endeavours to make its voice heard above every other. One is often surprised to hear it say words and make sounds which no one had taught it, and to which it was not suspected to have listened. It seemed to practise its lesson every day till night, beginning again on the next morning. It is while young that it shows this great facility in learning; its memory is then better, and the bird is altogether more intelligent and docile. This memory is sometimes very astonishing, as in a parrot which, as Rodiginus tells, a cardinal bought for one hundred crowns of gold, because it could repeat correctly the Apostle's creed; and M. de la Borde tells us of another which served as chaplain to the vessel, reciting the prayer to the sailors, and afterwards repeating the rosary."

It is probable that there are many varieties of this species of parrot in size as well as in colour, and they appear to be very abundant in the forests of the richer parts of western Africa.

Common Green Parrot (P. Amazonius). This is the favourite thick-bodied and short-tailed parrot of South America; but it should seem that there are many more varieties of it than there even are of the grey parrot. The colours of the one in greatest request are as follow: the bill blackish, the irides yellow, the forehead bluish; the head and throat yellow, but with bluish margins to the feathers; the general plumage bright green, inclining to yellowish on the back and the middle of the belly; the bastard wing red, the quills more or less mottled with green, black, red, and yellow, and the tail of nearly the same colours. It is, however, subject to great varieties of colour, some being almost entirely yellow, some brownish, and some yellow with red margins to the feathers. It is not very well ascertained which of the varieties is most remarkable for its colloquial powers, but the green one is the one which is most frequently seen in Europe, and it is one of the most easily procured of all the parrots. It is rather docile, and not difficult to be taught to articulate; but it is rather mischievous in the use of its bill in pulling its cage to pieces, destroying furniture, and performing various other mischievous operations. The parrot which we mentioned in a former part of this article, as piping the boatswain's whistle, and giving the word of command, belonged to one of the varieties of this species.

Green parrots of this species, or of others nearly resembling it, are found in vast numbers in tropical America, and especially in the rich woods which fringe the valley of the Amazon. They generally congregate near the margin of the waters, and lodge in the mangroves and other aquatic trees, where food for them is to be had at all seasons. They are much less frequently on the wing than the macaws and other long-tailed ræes; but they sometimes make their appearance on plantations near the woods, where they commit very serious depredations by mangling and destroying ten times the quantity that they eat. In a state of nature they are strictly vegetable feeders; but when kept in confinement and treated artificially, they show a partiality for animal food. Such food, however, if taken in any quantity, does not agree with them, it stimulates their digestive organs too much, and thereby injures their health. This is the case with all animals which naturally feed upon vegetables; and we believe that the converse holds good, and that vegetable food injures an animal naturally carnivorous, by stimulating its digestive organs too little.

The chief disease, however, to which these and all the other habitually climbing parrots are most subject, when most closely confined in cages, is a sort of goaty affection of the feet, obviously arising from too little exercise being afforded for organs which nature formed for very constant and very laborious action. When one of those parrots is described, all may be said to be described, with the exception of mere size and colour; but still we shall give a very brief notice of another one.

Festive Parrot (P. festus). This is an inhabitant of the same country with the common green parrot; but it differs so much, that it is well entitled to rank as a distinct species. It is larger, than the other, measuring about fifteen inches. Like that, it is a

green parrot, but the green is generally clouded with white, and there are other differences. The bill inclines more inwards at the tip of the lower mandible, and it is flesh-coloured; the nostrils are very conspicuous, placed in a cere at the base of the bill; a red streak extends from the nostril to the eye, and a very narrow one across the forehead, just above the cere; over and behind the eyes the feathers are glossed with bright azure; the external webs of the quills are deep blue, and the lower part of the back and rump are dark red; the tail is the same colour as the body, except the margins of the external feathers, which are blue, and a red spot near the base of each feather, except the two middle ones. When we speak of the tail of a parrot being squared over, all that is meant is, that the feathers are of equal length, for each individual feather in the tail and the wings, and their coverts, has its tip rounded off, and a firm and well-defined outline; and the clothing-feathers generally have their terminations flat circles. It is this peculiar form of the feathers which prevents them from being ruffled while the birds scramble about among the branches in the performance of their natural avocations. All those South American parrots are understood to nestle in the holes of trees, and to produce four white eggs in each hatch. The young, when they first break the shell, are white, callow, and naked, and they are first covered with down before their plumage begins to appear. The parent birds, therefore, require to feed them for a considerable time, and they do this with great assiduity and attention. The pair have also a strong attachment for each other, independently of the mere fact of pairing; and, indeed, parrots of all kinds are remarkably attached to their own species. It is this attachment which is the foundation of such teaching as they admit of; because those who attempt to teach parrots to articulate words, or to do anything else, always begin by endeavouring to gain their favour.

The anecdotes which are told of these birds are very numerous, and some of them have the appearance of being rather wonderful, but they are all easily explainable on the principle of common animal conduct without the slightest reference to the possession of reason or intellect. We shall not repeat any of the anecdotes, but proceed to another section of the family; remarking, as we pass, that there are several genera of short-tailed birds, approaching the parrots in size and resembling them in manners, which authors have described as different genera, if not groups, though it is not easy to arrange them in a manner quite satisfactory. We shall just mention one or two, which are so differently named and classed by different authors.

Grand Lory of Latham (P. grandis, Kühl). This is a bird of the eastern islands, and though not perhaps entitled, in strict propriety, to hold a place in the same genus with the parrots of Africa or of America, it is still more of a parrot than a lory, having the powerful bill and the fruit-eating habit of the former. No doubt it is a red bird, and the lorries are, generally speaking, red; but colour is only a trivial circumstance. The bill and feet are black, the upper mandible of the former arched and rounded in the culmen; the nostrils are hidden by the feathers at the base of the bill; the irides are yellow, and the cheeks completely feathered; the head and upper neck are rich crimson; the lower neck behind, the scapulars, the back, and the coverts of the wings and

tail, are scarlet, but with a dash of purple; the bastard wing and the primary quills are bright violet blue, the coverts of the latter being tipped with yellow, which is also the colour of the lower side and coverts of the tail; the fore neck, breast, and anterior part of the body, are clear lilac purple; the length of the bird, when full grown, is about fourteen inches, which makes it about the average size of the green parrots of South America, but it is a much more splendid bird in its colours. The young have the red parts mottled with green, which mottlings disappear as the birds approach to maturity.

Various other minor distinctions are made—such as the absence of the projecting angle or tooth on each side of the upper mandible, or the tail still shorter than it is in the typical parrots, and not reaching so far as the closed wings. The absence of the tooth denotes a bird living upon rather softer food, or, at all events, food in softer envelopes than that of the species which have the tooth; just as the carrion-feeding vultures have no tooth in their bills, while the falcons, which kill their prey, and eat it as soon as killed, always have the bill toothed. The short tail would seem to indicate a bird less disposed to ascending and descending than those which have the tail more produced; and the birds which have this structure are generally of powerful wing and lofty flight. We shall notice one as a specimen.

Robert Parrot—Latham (*P. Le Vaillantii*). This is an African species, and appears to be a migrant bird. It occurs on the eastern side of Africa nearly as high as the Cape, but we believe not in the vicinity of Cape Town. The ground upon which it is principally found is a wild country, subject to very heavy rains at one season of the year, and scorching drought at another. The naturalist after whom it has been named was its original discoverer, and he has given an account of its manners. It comes into those high latitudes of Southern Africa, during the warm and dry season, in large flocks; and appears to move northward, nearer to the equator, when the rains, and the evaporation thence arising, have reduced the temperature of the mountain forests. On their passages these birds fly at a great height, but are very clamorous withal in their flight, as is the case with all the discursive species of the parrot family. The screams which they then utter are their call-notes, and, like the rest, they appear to be social birds, and much attached to each other. They migrate southward for the purpose of rearing their broods; and, though each pair seek their own hollow tree for this purpose, a sort of intercourse is kept up among the whole. They are laborious birds, and regular withal in the distribution of their time. As soon as the sun rises they assemble on the tops of the trees, and spread themselves out to the morning sun for the purpose of evaporating the dews of night from their plumage. When this is done, they proceed in quest of their food, which is wild stone-fruit, of which they eat the kernel only. They continue at this feeding till about eleven o'clock, and then they resort to the waters, from which they are never very far distant, in order to enjoy the luxury of a bathe. This being done, they betake themselves to the close shade of the trees, in order to take their *siesta*, during the heat of the day, which they enjoy with the utmost silence: but, though they are silent, they are watchful; for if the report of a musket, or any other loud and unusual sound, is heard, the whole are very speedily on the

wing; and though, previous to the report, one would not suspect a single bird to be present in the trees, yet, the instant that it is heard, they rise in such numbers as to fill the air; screaming in loud and harsh tones, and flying with great rapidity. If undisturbed, they remain quiet during the mid-day, but come out again in the evening for the purpose of going in quest of their second meal, for they appear to take two regular meals in the course of the day. On their feeding excursions, and also at their morning bathe, they are usually in rather small parties; but, when supper is over, they assemble in much greater numbers, and proceed to bathe again. On their evening assemblings they appear all glee and hilarity, and literally exhaust the echoes with their screaming. Then, when they proceed to the pools and streams—to the pools especially, for few streams run in Southern Africa during the dry season—they tumble and sport about at the edge of the water, and splash and play in a very animated manner. When this assembly breaks up, the pairs proceed together, and every pair to their own hollow tree for the night; but they assemble again at sunrise, and the occupations of one day are simply a repetition of those of another. From this account which Le Vaillant gives of their daily occupations—and we should suppose that there is no reason to doubt his veracity—it is probable that those birds which breed during the dry season, in countries where the season is very dry, do not require to sit upon their eggs during the day, though they must do so during the night, in order to protect them from the dews, which form so heavily in those countries, and occasion such a reduction of temperature during the night. Upon turning to the article *OSTRICH*, the reader will find some remarks on the incubation of those birds which deposit their eggs in the free air on the naked sand; and it is not a little satisfactory to learn, that birds which build in the holes of trees, in countries having the same character of seasons, follow a practice nearly similar. These birds agree with the typical parrots in laying four white eggs about the size of those of pigeons, and both the male and the female are equally attentive to the nest. The young, on their first appearance, are quite naked, but they speedily receive a covering of greyish-coloured down, though six weeks elapse before they are in plumage. During all this time the old birds feed them with great assiduity, and appear to have the greatest affection for them.

These are highly interesting birds, from the regularity of their manners; but the colours of their plumage are not very striking. The head, the neck, and the breast, are dull olive green, darker on the upper part of the head, and marked by a black streak from the gape to the eye; the lower neck, the scapulars, and the coverts of the wings, are brownish-black, with green borders to the feathers; the rump, the belly, and the tail-coverts, both upper and under, are bright green; the turns of the wings, and the feathers on the tibiae, are bright reddish-orange; the quills and tail-feathers are brownish-black, glossed with green; and the naked parts of the feet and toes are grey. The active and regular habits of these birds give them a higher degree of interest than is possessed by those species which are habitually found in the same trees; and it would be very desirable to know to what regions they migrate when they quit Southern Africa during the rainy season. Unfortunately, however, we have no information upon

this point ; neither are we well informed as to the conduct of the birds in a state of domestication.

The next subdivision of short-tailed parrots to which we have to advert, consists of birds of very small size, but of great beauty and elegance. Systematic writers have bestowed upon them the generic or sub-generic name of *Agapornis*, the literal translation of which, "love-birds," is their common English name. They are not numerous in species, at least as hitherto discovered ; and, altogether, they are rather rare birds, though we believe some of them are, or at all events lately were, in the collection of the London Zoological Society at the Regent's Park. But it is to be regretted that, notwithstanding all their zeal and all their science, the managers of that society have placed their splendid collection of live animals in one of the very worst situations for natives of tropical countries, whether birds or beasts, that could possibly have been selected. Their gardens are on a most retentive part of the London clay ; and hence the climate is more trying to the constitutions of animals of dry and warm countries than if the gardens had been situated in Orkney. The matter is now beyond cure, however, because the gardens are established, and yield a profit as a mercantile speculation, which the author of this article believes was the first object in their establishment, notwithstanding the pain, disease, and death, which the damp and chilling atmosphere over the clay inflicts upon the unfortunate captives. *En passant*, we may perhaps be allowed to remark, that here is a strong feeling of the merchant running through all those establishments in the British metropolis, which profess to have for their object the advancement of science, and which furnish specimens of nature, or gimcracks in art, to feast the eyes of the wondering multitude. The pretended science may be zoology, or anything else ; but the real and substantial end is that of obtaining from the visitors as many shillings as possible. This is a disgrace to science and a shame to England ; and every man who loves knowledge, and the honour of his country, should assist in setting the brand of infamy upon it, and putting it down. But we must leave this most unlovely subject, and advert for a little to the love-birds.

We shall only notice two species, and they are both about the same size, or at least not greatly different from each other ; the one is a native of the eastern islands, and the other, we believe, of Africa, the African species being the smaller and handsomer of the two. The one of these is about six inches in length, and the other not more than five. Their forms and their bills are exactly those of the larger parrots ; but there is a difference in the texture of the general or clothing plumage of their bodies. The feathers in it are not formed into distinct scales, as they are in the large parrots, but close and resembling smooth and flat fur, like the feathers of other small birds. Their wings are rather short, and not so pointed as the wings of parrots ; their tails are also rather short, and round at their extremity, but they are proportionally broad. Little or nothing is known of their habits, though we can infer that they must be very short-flighted birds ; while the breadth and power of the tail show that they must have great power of ascending and descending.

Molucca Love-bird (*P. Moluccensis*). Though named after the Molucca group, or indeed after Malacca, by authors, it is probable that this pretty little

bird is pretty generally distributed over the Eastern Archipelago, though it is a bird which keeps close in the forests, and is in consequence very seldom seen. We must not wonder at those very small parrots keeping very constantly in the trees ; for the very smallest birds of our own country, the *Reguli*, or crested wrens, have the same habit ; and so close do they keep to the trees that one species, the red or fiery-crested, was never supposed to be a British bird, until a cat made the discovery some few years ago. The species of love bird in question has the head, rump, and upper tail-coverts blue, and the back blackish grey ; the upper wing-coverts are bordered with yellow, and the under sides of the wings are red ; the front part of the cheeks and the hind neck are whitish ash, and all the under parts yellowish ; the bill is red, and the feet grey. The total length of the bird is six inches.

Van Swinderen's Love-bird (*P. Van Swinderianus*). This is the species known by way of eminence as the love-bird. It is an exceedingly beautiful little creature, only about five inches in length, and understood to be a native of Africa ; but it is a rare bird, probably from the difficulty of getting a sight of so small a creature in the close foliage of the trees, which foliage it very much resembles in colour. Its head is thick and strong for its size, indicating the presence of powerful muscles for working the bill. The bill is deep chestnut brown inclining to black, and formed for the most powerful action in proportion to its size ; the upper mandible is very much arched, and the sharp tip projects far over the extremity of the under one ; the upper mandible is strengthened with margins, and, though it is not decidedly toothed, it has a flexure in the outline which amounts nearly to the same thing ; the top of the head, the cheeks, and the neck are beautiful green, terminating in a half collar of pure black on the back of the neck, which ends in a point on each side ; beneath this there is a collar of greenish yellow, which barely meets behind, but forms a pretty large gorget on the throat and upper part of the breast ; the back and wings, and also the under part, are of a pleasant green, though less brilliant than that on the head, and having a slight brownish or purplish tinge on the middle of the back ; the quills are black in the middle, with broad green borders ; the middle tail feathers are blue ; the remaining ones are red at their bases, then crossed by a bar of black, and afterwards dull green at the tips ; the rump and upper tail-coverts are bright blue, but when the wings are closed they are scarcely seen ; the tarsi and toes are blackish grey, and they are strong for the size of the bird. Nothing has been hitherto observed of the nest of this beautiful little creature, or indeed of any of its domestic habits. From their conduct in a state of captivity, however, it is clearly ascertained, that their attachment to each other is extreme ; and it is on this account that they have obtained the name of "love-birds." They are not the only members of the parrot family which evince a strong attachment for each other, for this is shown by many of the other species. But the love-birds are characterised, more strongly perhaps than any of the others, by appearing to live not so much for themselves as for their companions. If two are placed in the same cage, the one of them will not eat, or drink, or bathe, or rest on the perch, or do any one thing, unless the other does the same ; and if a portion of even the most favourite food is given to

the one, and none given to the other, that one instantly divides it fairly with its companion. This is a beautiful instinct; and perhaps it is not so strong in any other department of nature, as among the smaller members of the parrot family. In many animals we find other instincts, the strength of which we cannot fail to admire; but this is one with which we are not only delighted, but from the example of which we may actually learn to "love one another."

In the southern islands of the Pacific there are some members of the parrot family which retain the general shape of the parrots properly so called, and have the tongue large and fleshy like them, though the bill is differently formed, and the muscles which work it are less powerful. We shall mention only one of these, because much is still wanting before we can correctly determine what difference of habit is associated with the different structure of their most important organ, the bill.

Nestor (P. Nestor). This bird is a native of New Zealand; and it is almost as anomalous in the parrot family as some others of the New Zealand birds are in the families to which they are most nearly allied. It may possibly exist in Australia, and in some of the adjoining islands, but in the meantime we must consider it as a museum bird. Its general plumage is sombre compared with that of the parrots. Its head is more slender, its bill more elongated, and the upper mandible straighter; but it is about the size of the larger parrots, and in the character of the feathers it is dressed in a parrot's plumage. It is about fifteen inches in length; and the general colour of the plumage is reddish, passing into bronze in some parts, and into yellow or orange in others. The bill is lengthened, the upper mandible compressed and hooked at the tip, furrowed on the under side to receive the lap of the under mandible, which is compressed and but slightly convex in its outline. The wings are both long and broad; and the tail is of mean length, strongly fortified by coverts, square at the end, and having the points of the shafts of the feathers extending a little beyond the webs. The bill is brownish grey, with the tip of the upper mandible dusky; the front and top of the head are mottled with greyish white in different shades, with a trace of green; the cheeks and upper sides of the neck are yellow and red, and the feathers small and loose; the remainder of the neck and the under parts are dull red, with brownish green margins to the feathers; the upper and under coverts of the tail are deep red, and the wings and tail feathers are brownish green. Inhabiting a colder latitude than the typical parrots, this bird is less brilliant and more mottled in its plumage; but little or nothing is known of its habits.

All the varieties hitherto enumerated have the bill and tongue so formed as that they can subsist chiefly upon fruits, though it is probable that the last-mentioned one lives in great part upon farinaceous roots. There still remain a sort of two sections of the family which have the bill constructed for this purpose, but which differ from all those already mentioned in other particulars. They are chiefly natives of Australia, though some have been observed in the islands farther to the north and east. The most strikingly beautiful and characteristic section are,

COCKATOOS. These are very handsome birds, elegant in the form of their bodies, and with beautiful crests, which they can erect or depress at pleasure.

They are also birds of very gentle disposition, easily tamed, very susceptible to kindness, capable of a good deal of obedience, and not so prone to gnaw and do mischief as the macaw and parrots. They are not, however, capable of learning to articulate words with any thing like perfection, or even at all in most of the species, though they enunciate very distinctly the word "cockatoo," which has been adopted as their general name. There are as many known species of them as eleven or twelve; but we must content ourselves with a mere notice of one or two.

Great White Cockatoo (P. cristatus). This is a large and handsome bird, seventeen inches in length, and nearly as heavy as a common fowl. Its general plumage is white, except the primary quills and the outer feathers of the tail, which are sulphur-yellow on the middle of their inner webs. The bill is blackish, and the cere at the base of it is quite black; the irides are dark brown; the crest is five inches in length. It is a native of the eastern islands, and is often exhibited in Europe, where its manners are amusing, though its articulation is confined to the word already mentioned.

Red-crested Cockatoo (P. Moluccensis). This species is the same length with the former, but rather stouter; and it is a particularly handsome bird, though more shy than its congener with the white crest. It can hardly be taught to articulate words, but it imitates very readily the voices of various other animals. Its bill is bluish black, with a black cere; the irides are deep red; and the feet are leaden-grey, with black claws. The general plumage is white, but glossed over with a general blush of rose colour. The tuft, which can be either depressed over the hind head or erected, is very large, the feathers being six inches in length. Some of the feathers are orange on the under sides, and the middle feathers are red. It is a native of the eastern isles as well as the former, but it is a hardy bird, and bears easily the climate of this country.

Banks's Cockatoo (P. Banksii). This is a large and very splendid bird, measuring seven and twenty inches in length, though a considerable portion of that is occupied by the tail, which is much longer than in most of the cockatoos. Some authors have made it the type of a separate genus; and it certainly has peculiar characters. The crest, when in a state of repose, lies flat and concealed; and the upper mandible is so much hooked that the tip of it approaches near to the throat, while it is so broad that it almost conceals the under one. The bill is yellowish blue, the feet black, and the irides red. The prevailing colour of the plumage is black; but the cheeks and a portion at the base of the crest are mottled with yellow, and there is a tinge of yellow spotted over the under part. The wings are of the same colour with the general plumage, and so are the two middle feathers of the tail; but the lateral feathers, though blackish at the base and the tips, have the middle crimson, crossed by five or six bars of black. This bird is, however, subject to considerable varieties. It is a native of Australia, where it appears to be rather a rare bird, as but few specimens of it are brought to Europe.

Three-colour-crested Cockatoo (P. ———). This is rather a rare bird, but it is one of singular beauty, especially in the crest, which consists of ten principal feathers, five on each side, pointed, and standing apart from each other when erected. It is about eleven or

twelve inches in length. The general colour of the plumage is white, variously shaded with reddish chestnut, which is very deep on the under sides of the wings. The bill and feet are pale grey, and the irides bright reddish brown, showing very conspicuously in the comparatively pale plumage with which the eyes are surrounded. A row of feathers over the base of the upper mandible are scarlet, but the remainder of the plumage on the forehead is of the general colour of the body, the feathers being elongated, and forming a species of coverts over the bases of the principal crest feathers. These crest feathers are first bright brick red, then yellow, then bright red again, and ultimately white for the last half of their length, where they are lancet-shaped. This is an exceedingly handsome species, but unfortunately scarcely any thing is known of its history.

It is generally understood, however, of this and of all the other cockatoos, that they nestle in holes of trees, and have only two eggs in a hatch, which are white without any markings. They are vegetable feeders, and flock together after the young are hatched, at which time they levy pretty severe contributions upon the crops of the colonists inland from Sydney. They are wary birds, and place sentinels, as appears to be the case with all the ranging members of the parrot family; but the colonists shoot the young of various species in great numbers, and hold them in considerable estimation as game. So few particulars are known, however, with regard to the general habits of this interesting division of the parrot family, that there are not materials sufficient for forming even a guess at their use in the economy of nature, or the kinds of localities for which they are peculiarly adapted.

Resembling the cockatoos, in so far as having a crest upon the head, and partially also in the shape of the body, there are one or two species which inhabit the oriental islands, more especially New Guinea. Their habits in a state of nature are little known; but the form of the tongue leads us to conclude that they must be different from those of all the decidedly *frugivorous* members of the parrot family; for all of these have the tongue thick, fleshy, long, and smooth or simple at the extremity. The species to which we now allude have the tongue small, in the form of a little horny gland, surrounded by a sort of capsule, and supported upon a cylindrical peduncle of some length. From this slenderness of the tongue, as compared with the typical parrots, these birds have got the name of *Microglossus*, or little tongue; though what particular purpose this singular form of tongue answers in their economy has not been ascertained. We shall notice only one of them.

Gohath Aratoo (*P. aterrimus*). This is a very large bird, one of the largest, if not the very largest, of all the parrot family; and its aspect is rather repulsive. The general colour is blackish, with a dash of purple toward the head, and of green on the wings. A large space around the eye is covered with a naked skin, wrinkled, and of a red colour; in the midst of which the brownish yellow iris glares out in rather a formidable manner. The head is furnished with a crest of feathers, of slender form, and nearly of the same colour as the body; and these feathers the bird can erect at pleasure, though, when not erected, they give the head a shaggy appearance. This bird has been known for more than a hundred years; but

we are still in perfect ignorance as to its manners. We do not even know what it feeds upon; though the great strength of its bill, and the decidedly marked teeth in the upper mandible, lead naturally to the supposition that the work which it performs must be of no ordinary kind.

Though, in common with various others, we have applied the specific epithet, *aterrimus*, or the blackest, to this species, we believe it is not quite correct; for there is one still blacker as to external appearance; and *gohath*, the specific epithet adopted by Kuhl, may be better descriptive of this one. The difference in blackness does not, however, arise so much from the tint of the feathers, as from a grey powder which comes out in considerable quantity between the feathers of this one, and gives them a tinge of its own colour. The other is a much smaller kind, not above fourteen inches in length; and the bill and feet are rather paler than in this one. Both appear to be natives of the same countries, and their manners are equally unknown. It is possible that they may be merely varieties, or even the same bird; for it is stated that the skins which are distributed through the different museums of Europe, differ greatly in size, and not a little in the tint of the plumage.

There is another bird, exceedingly little known, and rarely to be met with except in the most extensive collections, which has the general air of a parrot, and a formidable bill, fitted for hard labour; but in its bill and head it differs greatly from all the rest of the parrot family. Wagler has made it the type of a genus, under the name of *Dasyptilus*, in consequence of its head being covered with hairs, rather than with feathers. It is a bird of pretty large dimensions, measuring about twenty inches in length, and being stoutly made. With the exception of the upper part of the neck and the head, the feathers have the character of parrot's feathers; and the feet also are those of a parrot. The bill, however, when seen in profile, appears to be something intermediate between those of a parrot and the beak of a bird of prey. It is of moderate height at the base, and pretty long, the basal part of the upper mandible being straight, though the point curves strongly over the lower one; which is narrow at the tip, with strong margins, and fortified with a keel along the middle. This bill and the shape of the head, together with its being covered with hair, and not feathers, give this bird a more ferocious air than the generality of the parrots; though it is still probable that it is a vegetable feeder. The cheeks and a portion round the eye are brownish ash, and nearly naked, being covered with only a few hairs. Above the eye there is a crimson spot, which is covered by hair, like feathers. The remainder of the head and neck are black, and thinly covered with feathers of the same kind, which do not conceal the skin. The tarsi are strong, but very short; and the toes and claws powerful. The scales on the tarsi are not imbricated, as they are in the majority of birds which live in trees, or on the dry ground; but reticulated, or placed in a net-work of connecting membrane, as they are upon the tarsi of wading birds. This particular covering of the head and upper neck, and of the tarsi, certainly points to some peculiarity in the habits of this bird; but what this peculiarity is it is impossible to say in the present state of our knowledge. The form and shortness of the tarsi, and the decidedly zygodactylic structure of the feet, are against the idea of the bird being in any respect a

wader. But farther observation must be made, before anything can be known respecting it. It clearly belongs, however, to the strong-billed division of the parrot family, and to those whose general habit is climbing. The breast, the upper parts, the wings, and the tail, with the exception of the coverts, are black; and the greater part of the wing coverts, the upper and under coverts of the tail, and the rest of the upper parts, are crimson. The bird is well furnished for flight both in the wings and the tail; and it differs so much from the mere typical parrots, that a knowledge of its habits would be very desirable.

There still remains a beautiful and highly interesting division of the parrot family, more delicate in structure, and also in feeding, than those which have been hitherto mentioned. This division comprises all those birds which are usually known by the name of

LORIES. The birds of this division are all natives of the east; and many of them are birds of great beauty and highly interesting manners. They are, however, more delicate in their nature than the macaws, parakeets, and parrots; and, therefore, though they are abundant in their native countries, there is some difficulty in bringing them alive to Europe; and a good deal of care is necessary in order to keep them alive after they are brought. The name "lory," by which the whole are popularly designated, is, like the word "cockatoo," the call-note of some of the species; though neither the one nor the other is the call-note of all the birds of which it has become the name.

The members of this division are inhabitants of the south-east of Asia, the Oriental Isles, and New Holland; and it has sometimes been proposed to subdivide them into *Lories* and *Lorikeets*—applying the former name to those in which the prevailing colour is red, and the latter to those in which it is green. It does not appear that much distinction of character would follow this distinction of colour; and, therefore, it is of little practical use, though there is a sort of geographical distinction between them; the red ones inhabiting nearer India, and the green and variegated ones more toward Australia, and the remote islands of the Pacific, some of them being found as far to the eastward as the Sandwich Islands.

They are all climbing birds, and have the feet as well adapted for that purpose as any of the parrot family. They differ considerably in their bill, however; and they all, in a great measure, agree with each other in those particulars in which they so differ from the rest. The bill is still much hooked in the upper mandible, and arched in the ridge of the lower one; so that any one who sees it, in any one of the species, would at once pronounce it to be a parrot's bill. It is, however, much smaller and feebler in proportion than the bill of a parrot; and the form of its acting surfaces points it out as adapted for a less severe kind of work. It is never toothed, scarcely ever margined, and the inside of the hook on the upper mandible has not the rough and file-like character of that of the nut-cracking parrots. The strong palatal ridges, which serve as a base of resistance, against which the lower mandible acts when compressing a large nut, are also wanting; and the whole structure of the organ points out that the lories could not by possibility subsist in the same manner as what one may with propriety call the "hard-mouthed parrots." There is a difference also in the tongue. With the exception of the *microglossi*, the precise use

of whose very peculiar tongue is, as we have said, not known, the whole of the hard-mouthed parrots, by what name soever they may be called, have the tongue full and smooth at the point, and they use it with great dexterity in keeping the food against those parts of the bill which can divest it of its hard covering. The tongue of the lories, on the other hand, is slender, soft in its consistency, more or less covered with projecting papillæ, and sometimes those papillæ form an absolute brush at its extremity. We find the tongue similar to this in those birds of a different order, which sip or suck the nectar or honey of flowers; and we naturally conclude that such, in part, is the use of this structure of tongues in the lories. The honey of flowers, and the sweet juices of pulpy fruits are the substances upon which the lories feed; and the countries which they inhabit abound greatly in such substances. The mango, the mangosteen, the banana, and a countless number of others, grow in great profusion in forests of the Oriental Isles, and furnish the beautiful birds of this section with an ample supply of food, so that they leave the kernels of fruits to the hard-mouthed tribes, and very rarely, if ever, attempt breaking the shell of a nut. The Australian ones fare somewhat differently, for Australia naturally furnishes scarcely one pulpy fruit; and, therefore, the birds of this division, which inhabit there, subsist chiefly upon the nectar of flowers, and have the extremities of their tongues fringed with longer papillæ than the birds of the eastern isles.

The beauty and elegance of this section of the parrot family, their geographical distribution, and the peculiar office which they perform in nature, all tend to give them a high degree of interest; and we regret that the space to which we are restricted will not allow us to enter into the details of their characters, either general or particular. We may hint, however, that, in the tails and general forms of the lories, there are resemblances to several of the divisions of those parrots which eat hard fruits. Some of those which have been denominated lorikeets bear a slight resemblance to the macaw family; others have the tail short and the body thick, more resembling the common parrots; and there are also some which have the body slender, and the two middle feathers of the tail much longer than the others, in the same manner as the arrow-tailed parakeets; nor are there wanting some, which, in size and in the general form of the body, and even in the colours, have no inconsiderable similarity to the "love-birds." Under all those shades of difference among themselves, and of agreement with different sections of the nut-breaking and kernel-eating divisions, they are still, however, constant to their essential character, namely, that which determines the nature of their food; and we should, perhaps, make as rational a popular distinction as any, if we considered the birds already described as strong-billed parrots, and the lories and their allied races as weak-billed ones. We must, however, close our general remarks, and proceed to mention a few of the species.

Purple-caped Lory (P. dominella). This is a very beautiful bird, one of the most typical of the true lories, or those which have a general resemblance in form to the characteristic short-tailed parrots. There is a wide distinction in the body plumage, however, to which it is desirable, and even necessary, to attend. The plumage of the parrots is all over firm and scaly,

whereas that of the lorics is soft and downy, excepting on the wings and their coverts. The clothing plumage of birds is far from the worst index to their general habit. A bird of gentle labour always has the plumage of the soft and downy character, whereas one which has to rough it, whether in field or forest, or in the sky, invariably has the individual feathers firmly set. This bird is a native of the eastern islands, of which it is one of the principal winged ornaments. Its size is about the same as that of the grey parrot, namely, between ten and eleven inches in length. The bill, which is not very large, and has no notch in the upper mandible, is yellowish orange, with a blackish cere at the base, in which the nostrils are pierced; the feet are dark grey, and the claws black. The head is flat on the crown, and occupied as far as the eyes, but not over them, by the cap. This cap is very dark purple at the base of the bill; but passes gradually into very delicate violet, as it approaches the back of the head. The general plumage of the body is a very fine red, intermediate between scarlet and crimson, with the exception of a gorget of pale reddish yellow, in the form of a crescent, between the throat and breast; but this gorget is very obscure in some of the specimens. The external margins of the quills and the lesser coverts of the wings are deep blue, passing into sky-blue. The others are yellowish green relieved with lighter. The primary quills are beautiful blue, and the secondaries yellowish green; but, when seen at a little distance, the whole wing has a green appearance, which, being the complementary colour of the red on the body, makes both show off to the greatest possible advantage. The feathers on the tibiae are sage-green. The tail, which is rather large and firm, has its extremity formed into a very perfect half-oval. The tips of the feathers are reddish orange; within that there is a crescent of deep brown, almost black, and the remaining part of the feathers is nearly the same red as the body, only a little more inclining to purplish brown. The female bird is less in size than the male; the gorget is obscure or wanting; and there is no blue in the wings, except a slight mottling along with green on the margins. Sometimes, however, this species breaks into coloured varieties.

It is one of the best-tempered and most desirable of all the parrot tribe; but it is very delicate, difficult to be brought alive to Europe, and, therefore, scarce as a living bird. It never uses its bill in any work of destruction; and it is remarkably docile, and highly susceptible of every species of kindly attention. "Lory" is its habitual cry, in the use of which it is by no means sparing; and it also articulates tolerably well, though in a hollow voice; but it whistles with great clearness, and very readily acquires a knowledge of any tune. As its voice, though very incessant, is not so loud as that of the parrot, it is a very desirable bird for those who are fond of amusing themselves with such creatures; but, in consequence of its delicacy, it is high priced, and a good deal of care is necessary in order to keep it alive in European climates.

Ceram Lory (P. garrulus). It is probable that this species obtains its trivial name from having been first brought from the island of Ceram. It is not, however, confined to that island; for it is found in others of the Molucco group, and probably through the Oriental Islands. In size it very much resembles the species last mentioned, namely, that of a common

pigeon; and its manners and delicacy of constitution are nearly the same. It is, however, subject to very considerable varieties of colour, on which account it is in danger of being described as several species. The following are the colours which most frequently occur: the bill orange, the cere and naked circle round the eyes grey, the irides deep yellow, and the feet brown. The clothing plumage is bright red; but the lesser coverts of the wings are mottled with green and yellow. The primary quills are deep green on the outer webs, red on the inner webs, and grey at the tips. The two centre feathers of the tail have three colours: brown at the base, red in the middle, and green at the tips. The next pair have more than half the length from the base red, and the remainder green; and the four external ones, on each side, are red at their bases, violet in the middle, and green at the tips. Except in colour, this bird resembles the former species very nearly; and its disposition is also very much the same.

Black-caped Lory (P. Lory). This species has usually been brought from a more northerly latitude than either of the two preceding ones, namely, from the Philippine Islands; but whether it is merely a climatal variety of the purple-cap, or a distinct species, has not been very clearly ascertained. In Europe it is a very rare bird, and is on that account highly prized; but its disposition and manners do not appear to be either better or worse than those which we have already mentioned. Its colours are, however, different from either of these; and, though they are subject to some variety in different species, the following may be taken as the most common: the bill and irides orange, and the cere and circle round the eyes dark flesh colour; the feet black, and the cap on the head bluish black; the general plumage of the body scarlet, but with a blue spot at the setting on of the neck, and another at the lower part of the breast. The general colour of the upper surface of the wings is green; but the inner webs of the quills are yellow, passing into dark brown toward the tips; and some of the secondary quills have yellow margins to both webs. The under coverts of the wings are red. The tail is blue on the upper side, with the exception of the two middle feathers, which are dark green; and the under side of the tail is yellowish. The feathers on the tibiae and those on the under parts, backwards, are bright blue. The colours of this bird are remarkably beautiful; but we know nothing of its manners farther than we do of those of the section generally.

Papuan Lory (P. Papuensis). This is one of the most elegant birds of the whole parrot tribe, both in the form and in the colours of its plumage. In the structure of the bill and tongue, and also in the general red colour of the clothing plumage of its body, it resembles the lorics to which we have already alluded; but the form of the body is much more elegant, and the tail is particularly handsome. The whole length is nearly eighteen inches, of which the two middle feathers of the tail measure about twelve, leaving not more than six for the length of the body. Those long feathers are narrow, and rounded at their tips; and the remaining feathers of the tail, five on each side, are so graduated, as, with the exception of the two long ones, to make the outline of the extremity of the tail but very elongated half-oval. The longest of these feathers are not above one-third the length of the two middle ones; and the lateral ones

are about two-thirds the length of those nearest the middle ones. They are all rather broad, very firm in their texture, and very firm at their terminations. The two middle ones are delicate grass green for nearly two-thirds of their length from the base, and delicate yellow for the remaining part. The lateral feathers are darker green, for about the half of their length, and deep saffron yellow for the other half. Taken altogether, the tail is one of the most beautiful appendages to be met with in the whole of the feathered race. The general plumage of the body is a very brilliant, though rather deep, red; but it is variegated by markings of brilliant azure. Of this colour there is one well-marked spot upon the hind part of the head, reaching nearly from eye to eye; and another on the nape. These two spots are rendered still more brilliant by each of them having a margin of deep purple, inclining to black. The lower part of the back, the rump, and also the feathers upon the tibiae, are also azure; and in some species there is a little white or yellow below the turn of the wing. The wings are green, passing into darker on the inner webs of the primary quills, which are almost black. The bill is reddish orange, with the tip of the upper mandible extending far over that of the under one; but it is a light and delicate bill, and the projecting tip is not nearly so much hooked as in the parrots. This is indeed one of the most beautiful of birds, in every point of view in which it can be taken. It is a native of that country which is the grand headquarters of the birds of paradise, and which is perhaps richer in its ornithology, and also in its vegetable productions, than almost any other country on the face of the earth. It is, therefore, seriously to be regretted that the character of its inhabitants is such, that no naturalist can explore it, or even venture to land upon it, without almost the certainty of being murdered. This is the more to be regretted, because it occupies a very peculiar situation on the globe. Its coasts are not yet wholly discovered: but enough has been observed to show that it is an island, or islands (for the fact of its being or not being intersected by the sea has not been ascertained), of large dimensions. It meets the regular wind and current of the Pacific from the east, and also the current which is turned north-eastward by the great coral reefs which stretch away to the south. The means of fertility are thus concentrated upon it; and there is no question, that, were there any means whereby it could be opened to scientific investigation, New Guinea would more richly repay the labour than any other spot on the face of the earth. It is especially remarkable as a station in the annual movements of a vast number of exceedingly splendid birds, which move in countless multitudes between it and the lands to the north and west, at one season of the year; and between it and the fertile spots on the east coast of New Holland, in another. It is highly probable, that, besides the species which we have just mentioned, this island may contain various other species of lorries equally splendid; and until favourable circumstances arise, under which its natural history can be explored, the eyes of naturalists, and especially of ornithologists, will be directed towards it in the most anxious manner.

We must now direct our attention farther to the south and to the east—to New Holland, and to the remoter isles of the Pacific, where succulent fruits are not so abundant as they are in the native localities of

the red lorries, a few of which we have enumerated, and where, in consequence, birds of this section must be adapted for finding a different sort of food.

It is here that we meet with those beautiful birds of very varied plumage, still resembling the lorries, properly so called, in the general form of the bill, but having the tongue differently constructed. In the lorries the papillæ on that organ are short and soft; but in the birds now to be considered they are of considerable length, drawn out like firm and elastic ends of thread, and sometimes forming a tuft round the extremity of the tongue like a little cylindrical brush. On this account some have regarded these birds as a distinct genus from the lorries, and applied to them the generic name of *Tyichoglossa*, or “fibrous tongues;” but this is perhaps a refinement in systematic arrangement which is of small value in a popular point of view.

If these birds are to be taken as a genus, they may be characterised as follows:—The bill smaller in proportion than in any others of the parrot family, compressed laterally, weak in its structure, and with but a slight convexity in the lower mandible, though in some species the tip of the upper one extends a considerable way over it; the margins of both mandibles are in every instance thin and smooth, without any tooth, or other armature, by means of which the birds could break a hard or a tough substance; the wings are of moderate length, narrow and very much pointed, the first quill in each being the longest; but the webs of all the quills are very firm and entire, so that the wings are powerful ones, and far more ready than if they were of larger dimensions; the tarsi are short and stout, and feathered a little beyond their articulation with the tibiae, affording protection to the muscles and their tendons; the toes are also large, offering a broad base for rest; and the claws are sharp, strong, and crooked; the tail, in most of the species at least, is long, very strong at its insertion, and generally tapering nearly to a point. Altogether, the birds are remarkable for the compactness of their forms, and they are by no means inferior in the beauty of their plumage. Their food, in great part, consists of the honey which they extract from the nectaries of flowers by means of the fringed appendages to their tongues; and their subsisting upon a food so light, and obtained in such small quantity from any individual flower, requires the laborious use of their very neat and clever organs of flight. If we are to compare the tender-billed members of the parrot family with those which have the bills robust and fitted for severe labour, we should be inclined to say that there is the same resemblance between these birds and the parakeets, which have not the middle feathers of the tail produced, as there is between the short-tailed lorries and the parrots properly so called. Some have gone a great deal farther than this, and, in the visions of the night of their own nonsense, have seen representations of all the birds under the canopy of heaven in the different varieties of the parrot families; but the gentlest appellations which can be applied to such pretended discoveries is, that they are gratuitous nonsense. We shall now advert to one or two of the species, and we shall use the word lorikeet as the general English name.

Blue-bellied Lorikeet (J. hæmatodus). This is an Australian species, and an exceedingly beautiful and characteristic one. It is not a very large bird, being only thirteen inches in length, of which the tail

occupies only a half; but the head, body, tail, and wings, are well proportioned; and it is a remarkably pleasing bird to look at. In the living bird, the bill, which is rather small and handsome, is of a rich golden yellow, but, as is very apt to be the case with bills, it fades to a much duller colour after the bird is dead; the feathers on the head and throat are stiff and awl-shaped, and of a fine purplish blue, which changes its colours as the light falls differently upon it; on the throat the feathers lose their pointed character, and on the breast their terminations are flat curves; the lower part of the neck and the breast are deep red, passing into rich yellow toward the shoulders; the middle of the belly is rich purple, and the feathers toward the sides deep red, bordered with bright green; the feathers on the legs are bright red, and the under tail-coverts are red at the base, yellow at the middle, and green at the tips; the under sides of the wings are also red; the upper plumage is bright green in its general tint, but the feathers on the lower neck are red at the bases and yellow at the tips; above these there is a demi-collar, more or less distinct, sometimes pure yellow and sometimes inclining to green; four feathers in the middle of the tail are entirely green, and the remaining ones have their inner webs yellow, the portion of yellow increasing as the sides are approached; the quills are dusky green on their inner webs, and each is marked by a yellow spot. These very beautiful birds are natives of Australia, where they sip the honey from the flowers of various species of eucalyptus trees, which are very common in the forests there. It does not appear that they eat kernels of any kind, or do the smallest harm to the plantations of the colonists; and as they are quite harmless in wild nature, so they will not live for any length of time in a state of confinement. The colonists about Sydney have been remarkably successful in cutting down the forests of eucalyptus, and, by necessary consequence, they have equally thinned the numbers of these beautiful birds.

Parti-coloured Lorikeet (T. vernicolor). This is another handsome Australian species, but it would seem that the vocabulary was exhausted before it got its name, as its plumage is much less diversified than that of the preceding one. The bill and top of the head in this one are red; the throat, and a brush of pointed feathers behind the eye, yellow; a brush of the same kind of feathers, beginning from the bill to the eye, and extending to the lower neck, are blue; the lower neck and breast are deep but dull red; and all the rest of the plumage is dark green. As is the case with many others of the family, the caterers for museums have got the skin of this bird, and, in their own appropriate language, they have "set it up;" but of its manners nothing is known. The probability, however, is, that, from the similarity of structure between its bill and tongue and those of the last species, it also lives principally upon the honey which it extracts from flowers.

Orange-winged Lorikeet (T. pyrropterus). This is a small species, not exceeding seven inches and a half in total length, of which between two and three are occupied by the tail; but it is a pretty little bird. The bill is whitish, with a slight tinge of pink, and the upper mandible projects far over the under one, and is very sharp at the tip; and the edges of the bill are more margined than in some of the larger species; there is a white space round the eye, the iris of which is brown; the head is greenish blue,

fading into whitish on the upper neck, and again into green, which is the general colour of the body, but the whitish colour makes a sort of holly collar on the neck; the wings are greenish-blue on the under sides, with the exception of the smaller coverts there, which are very bright orange, or fire colour; the upper sides of the wings and the tail are green and yellow, and the feet are dull reddish.

This is a very seaward bird, being most plentiful in the Sandwich Islands; and when the late king and queen of those islands came to England, where they unfortunately lost their lives, they brought some of these birds along with them. This gave the zoologists of the day an opportunity of examining the birds, and also of settling their locality, which had at first been erroneously supposed to be South America. "In their manner," says Mr. Vigors, "they are peculiarly interesting. Strongly attached to each other, like the individuals of the small species so well known in our collections, and which we familiarly style *love-birds*, they assert an equal claim to that title, if it is to be considered the reward or the distinctive sign of affection. They will not admit of being separated even for a moment; and, whether in their cage or at liberty, every act and movement of the one has a reference to the acts and movements of the other. They are lively, active, and familiar, distinguishing and following those who attend to them with perfect confidence, but *always in concert*. Their movements are less constrained than those of parrots in general, approaching, both on the ground and on the wing, to the quick pace and short and rapid flight of the more typical perchers. They have apparently less power of voice than the greater part of the family, uttering only a sort of chirrup like that of the sparrow. This is shrill, it must be confessed, at times when rivalry, or any particular incitement, induces them to exert it to the utmost; but at other times it is far from unpleasant, more especially when they employ it, as is their custom, either in welcoming the approach of the morning or acknowledging the attentions of favourites.

Somewhat allied to these last-mentioned species in appearance and structure, are several little parrots scattered over the groups of islands in the Pacific. They are, generally speaking, characterised by the small size of the bill, which, however, still retains the parrot form; and by the appendages to the tongue, which are long and surround the apex of that organ much in the same manner as the petals of a flower. Generally speaking, they are birds of powerful wing for their size, and their tails are very stout, rounded in the general outline of the extremity, and also in the tips of the individual feathers, and strongly supported by coverts. The coverts of the wings have the scaly character of parrot's feathers; but the clothing of the body is loose and silky. Though decidedly of the parrot family, from the form of the bill, every species of these appears to require a distinct generic situation. We might perhaps be prepared to expect this, inasmuch as the birds live far apart from each other, and as the islands of the Pacific differ greatly in their characters; but the data are still too scanty for enabling us to form any thing like a correct natural history of those singular parts of the world. Authors have called one of the forms *Coriphilus*, and another *Psittaculus*, and we shall neither dispute the names nor question the propriety of their application.

Kühl's Coriphilus (C. Külli). This is a native of

Otaheite, and it is a very handsome little bird. Its bill is slender, and rose-coloured. The top of the head is yellowish-green, behind which there is a crest of bright purple feathers, which the bird can erect when it is excited. The remainder of the upper part is green, passing gradually on the rump and upper coverts of the tail; the tail feathers are deep green with a purplish tinge, and slightly margined with pale yellowish green; the cheeks, fore neck, breast, and under parts, as far as the feathering of the tarsi, are deep red, the feathers being loose and flocculent, and the under coverts of the tail are yellow.

In the same group of islands there are some other birds, apparently of the same genus, but differing from this one in their colours. Some of these have blue where this one has green and yellow, and white where it has red; and others are variously coloured. Their habits appear, however, to be exactly the same, and they subsist entirely or chiefly upon the honey of flowers, of which there is a constant supply in those islands of perpetual summer. They are clever on the wing, and altogether very delightful little birds. Their voices are also soft and murmuring, and without any of the harshness which characterises the sounds emitted by the hard-billed parrots. Some specimens of them have been brought alive to Europe, but we are not aware that any attempt has been made to teach them to articulate.

Blue-crowned Little Parrot (P. vernalis). This bird is a native of the Philippine Islands, and it is a very pretty little creature. Its length does not exceed four inches and a half, but it is a perfect miniature of a parrot. In the young birds the greater part of the plumage is green, but in the full-grown male the top of the head and the under sides of the quills and tail feathers are blue. The lower part of the back, the rump, and the upper tail coverts, are deep red, and the feet and toes are black. In the full-grown male also the throat is red, and there is a demicollar of yellow on the hind neck. In many of the islands of the Pacific there are various species of these *psittaculi*, or little parrots, not exceeding in size the common little birds which we meet with in our own country; but their history and manners are very little known. It should seem, however, that the whole of them subsist chiefly on the sweet juices which they collect from the nectaries of flowers; and as they float about over the cocoa-nut trees, and other evergreens of the countries which they inhabit, they are very amusing little creatures.

There still remain some very peculiar species of the parrot family which inhabit the south, especially New Holland and Madagascar. Their place in the system has not been very clearly ascertained; but one portion of them have got the name of *Platycercus*, from the breadth and extensibility of the tails; another has been called *Nanodes*; and a third, *Peroporus*, from being found chiefly upon the surface of the earth, and not perching upon trees. Little or nothing is known of the rest of them, and this article has already extended to such a length that we shall content ourselves with merely noticing a single species of each of the subdivisions to which we have alluded.

The Platyceræ, or broad tails, are inhabitants of New Holland; and, though their bills are small, they belong to the hard-billed parrots, rather than to those which follow in the train of the lorées. They are chiefly found in New Holland, where they attack the

plantations in great flocks, and do considerable damage; but some of them are highly relished as game.

One species, which has been denominated Pennant's broad tail, is called a lory by the settlers of Australia, because its general plumage is red. The tail is blue, however, and so are the coverts and turns of the wings, and a peculiarly formed whisker descending from the gape. The total length is about sixteen inches, but half of that length is occupied by the tail. It is a very pretty bird, and sometimes kept in cages for show, but it does not appear to be capable of much education.

Another species, which is much more beautiful in its plumage than the former, has been denominated *Pale-headed*. It is found in some parts of New Holland, but much more abundantly in New Guinea. The tail is very long and broad, the two middle feathers green, and the rest violet, almost white at the margins. The tibiae and under part backwards have their feathers deep red. The rest of the lower part, as far as the neck, is violet; the wings are blue, the upper part yellow, with the centres of the feathers dusky; and the head and neck dull white, more or less relieved by yellow.

The species to which the name of *Nanodes* has been given are very pretty little birds. They can perch; but they are also clever walkers, and in one at least, the parrot form, with the exception of the bill, is entirely departed from. The species to which we allude is the waved or undulated one (*N. undulatus*). It is a pretty little bird, about seven inches in length, of which the tail occupies half. The general colours are greenish, yellow, and brown, with blue on the middle feathers of the tail, which are very much produced; and there is a small patch of blue on each cheek. This handsome little bird is very common in New Holland and Van Diemen's Land, and appears as often upon the ground as on trees. There are several other species, some of them approaching much more to the form of parrots, or rather perhaps of maccaws; but they are much more ground birds than any of these, though they eat seeds rather than soft and pulpy substances. We have space left only for one other species,

The Grand Parrot (Peropterus formosus). This is a remarkable instance of a zygodactylic bird adapted for walking on the ground. The tarsi and toes are very long; and the claws upon the latter, instead of being hooked, as they are in the tree parrots, are comparatively straight. The bill is small and short, but decidedly that of a parrot, with the upper mandible much hooked, and the lower one much arched. The general tint of the plumage is green, but much barred and mottled with black and yellow. The wings are of moderate length, but the tail is very long and pointed. This bird is found in New Holland, and more especially in Van Diemen's Land, where it generally inhabits what is called the "back," that is, the places which are covered with low shrubs. It does not perch upon trees, but runs upon the ground among them; and, when it is raised, it has a leaping flight, and very speedily alights in another part of the bush. Its manners are, however, very imperfectly known.

Such is a slight outline of the parrot family, unquestionably the most peculiar and most interesting of the feathered race, and also one of the best defined. In the course of our few and slight remarks, we have

seen that these birds admit of a natural division into two great sections, the one of which feeds entirely upon the kernels of fruits, and the other upon sweet juices. We are disposed to consider the macaws as taking the lead in the first of these divisions, and the red-coloured lorises as taking the lead in the second. There are, however, many difficulties in the way of any thing like a natural arrangement of the parrot family; and to attempt following the systematists through their artificial fancies would be worse than useless. We have endeavoured to embody the principal points, and to notice the most characteristic species, and having done so we shall close this article.

PARSNEP is the *Pastinaca sativa* of Linnæus, a well known culinary plant long in cultivation. It is a nutritious vegetable, and contains so much sugar, that a very palatable and useful wine is made of its fermented juice. Its culture is extremely easy. The seed is sowed on deeply digged or trenched rich soil in March, either in drills fourteen inches apart, or broad cast. At the end of April, or during the month of May, the plants are thinned out to nine-inch distances apart, and being kept free from weeds during summer by repeated hoeing, are fit to be taken up and stored for winter use in October.

PARSONIA (Dr. Brown). A genus of tropical climbing plants, bearing pentandrous flowers, and belonging to *Apocynææ*. This genus was called *Echites* by Jacquin and Swartz.

PARTRIDGE. See **GALLINDIÆ**.

PASQUE FLOWER, is the trivial name of the *Anemone pulsatilla* of Linnæus. It belongs to *Ranunculaceæ*, and is a native of Britain, found on chalky pastures.

PASSALUS (Fabricius). A genus of coleopterous insects, belonging to the section *Pentamera*, and family *Lucanidæ*, and forming a distinct subfamily *Passalidæ*, having the antennæ slightly elbowed at the extremity of the basal joint, the body long and depressed; the upper lip distinct, the lower jaws corneous, and with many teeth, and the abdomen, as it were, pedunculated, as in the *Scaritidæ*, which this family appear to represent. This genus is confined to America, Asia, and New Holland, none of the species having been discovered in Europe or Africa. They are of considerable size, and black colour, the specific differences being very difficult of investigation. Madame Merian informs us, that the larva of a species which she has figured, feeds upon the roots of the batatas. The perfect insect is not rare in the sugar plantations. About fifty species are described by M. Percheron, in his Monograph upon the family just published.

PASSERINA (Linnæus). A genus of plants so called from their seeds having beaks like those of sparrows. They are shrubs and undershrubs found at the Cape of Good Hope, and belong to the eighth class of Linnæan botany, and to the natural order *Thymææ*. They succeed well in our greenhouse collections, and under the ordinary management.

PASSIFLORACEÆ. A conspicuous natural order containing six genera and above eighty species. The genera are arranged in two tribes, the first *Paropseæ*, containing *Smeathmannia*; and the second *Passifloræ veræ*, comprising the other five genera, viz. *Passiflora*, *Muruciua*, *Tacsonia*, *Diemima*, and *Modecca*.

The passion flowers and their immediate allies are herbaceous or shrubby plants, rarely trees, with often

twining scandent stems, and alternate simple, petiolate leaves, either entire or lobed, and usually furnished with glands and stipules.

The inflorescence is axillary, and the peduncles in the non-climbing species are all floriferous, but become in the climbing ones converted into tendrils. The flowers are showy, regular, and united, rarely separated by abortion, usually solitary, seldom aggregate, and for the most part invested with a triphyllous involucre. The calyx is free, with from five to ten sepals, the external ones herbaceous, the inner petaloid, and constitute a tube of various degrees of length, which is lined by filamentous or annular processes forming a nectary; the petals when present are five in number, and exerted from the throat of the calyx; the stamens are five, surrounded by numerous barren filaments, forming a radiant circle, arranged in one or two series; the filaments are shortly monadelphous, and opposite the external lobes of the calyx; the anthers versatile or peltate, two-celled, and opening lengthwise; the germen is free, borne on a stalk, one-celled, and many ovules; the styles are short or none, and the stigmata are thick, or lobed, or dilated. The fruit is a berry or capsule, either naked or invested by the calyx; when capsular it opens by valves; when a berry it is indehiscent.

The *Passifloraceæ*, although in general innoxious, are suspicious plants; for one species, the *Passiflora quadrangularis*, is known to be deleterious, and the others have not been sufficiently examined to allow their innocence to be affirmed, notwithstanding the fruit of most of them, even of the noxious one, is eatable. *P. malaformis* is the sweet calabash of the West Indies, where it is much esteemed as a dessert; and the fruit of *P. alata*, *coccinea*, *edulis*, *laurifolia*, *ligularis*, *ornata*, *tinifolia*, and *cærulea*, are all likewise esculent. The part which is eaten is either the fleshy arillus or the juicy pulp which surrounds the seeds. This succulent matter is fragrant and cooling, and has a pleasant flavour. It is mostly sucked through a hole made in the rind.

The name, passion-flower, owes its origin to some imaginative Jesuit, who fancied he had found an allegorical representation of our Saviour's passion, or, at least, of the instruments of torture, as well as other attendant circumstances in the structure of the blossoms, leaves, and tendrils of these curious and beautiful plants. There are a great number of species, and also many varieties, in our collections, the latter being hardier, and bloom more freely than the species; all requiring a good deal of room, as they soon cover any trellis or column against which they may be planted. They grow best in a mixture of loam and heath-mould, and are readily propagated by cuttings.

PASTINACA (Linnæus). A genus of herbaceous plants, mostly biennial, and natives of Europe. The flowers are pentandrous, and are ranged from their mode of inflorescence among the *Umbelliferae*. A large species, called the cocquaine, is cultivated in Guernsey and Jersey for feeding cows, and hence it is supposed is derived the richness of their milk. *P. opopanax* is a medicinal species, as well as several others. See **PARSNEP**.

PATERSONIA (Dr. Brown). A genus of Australian herbs, belonging to *Iridææ*. The flowers are pretty, and are commonly cultivated like Cape bulbs, that is, potted in sand and moor-earth, and kept in a cold frame; or, if planted in the open

border, they must be well guarded from frost in winter.

PAULLINIA (Schumacher). A genus of tropical American evergreen climbers, bearing octandrous flowers, and belonging to the natural order *Sapindaceæ*. Generic character: calyx of five sepals, imbricated, and persisting; petals four clawed, with scales at the base; two or four glands between the petals and stamens; stamens unequal; anthers oblong, fixed by the back, and two-celled; style thickish, short, and connivent; capsule pear-shaped, three-sided, and three-celled. The species thrive in our stoves in light soil, and are propagated without difficulty.

FAUSSIDÆ. A very extraordinary family of coleopterous insects, placed by Latreille amongst the *Xylophagous Tetramera*, but having a nearer relation to some of the aberrant *Necrophaga*. In this family the antennæ are of a very large size and singular form. In some of the genera they are composed of only two or three joints, the last being nearly as large as the rest of the body, and very irregularly constructed. The body is of small size, and depressed; the palpi are large, the maxillary having the second joint greatly dilated; the maxillary and labial are of unequal size; the elytra are square at the tips; and the tarsi short, and not bilobed. These insects are exceedingly rare in collections, and highly prized on account of the singularity of their form. They are exclusively confined to the old world, and are found in tropical Africa, at the Cape of Good Hope, in the East Indies; and more recently a species has been discovered on the Balcan mountains, which is described in the last part of the Transactions of the Academy of Hungary. Nearly thirty species (being about twice the number previously known) are described in a memoir published in the sixteenth volume of the Linnean Transactions, and about a dozen additional species are intended for publication in the forthcoming number of the Entomological Transactions. They constitute several very well-marked genera, varying either in the structure of the mouth or the number of joints in the antennæ. The type of the family is the *Pausus microcephalus* of Linnæus, about one-third of an inch long, and an inhabitant of Guinea.

PEA is the *Pisum sativum* of Linnæus. A well-known leguminous plant, extensively cultivated both in the garden and field. The garden varieties are very numerous, and the earliest crops, appearing at table about the beginning of May, are highly valued. Peas are sown once or twice in every month, from October to the beginning of July, yielding pods from the first of May till the middle of November. The latest crops are, however, precarious, and only valued in high cookery.

PEACH is the *Persica vulgaris* of Miller, a well-known wall-fruit, and one of the most esteemed in our desserts. It is difficult to state, with certainty, whether the peach, with its variety, the nectarine, are natural, or only accidental creations. They cannot be reproduced from seed with certainty; for, although all our best varieties have been obtained from seed at different times, and in different countries, yet no dependence can be placed on raising good peaches from their kernels. In this respect they are like our orchard fruits, and require to be budded on plum-stocks to perpetuate the best varieties.

In raising peach trees for bearing, very much

depends on a proper choice of stocks. This is particularly the nurseryman's business, who, for his own credit, will take care to place the different sorts upon the most congenial stocks.

Next to the necessity of choosing proper stocks is the preparation of the border to receive the young trees, either in the first, second, or third year after they have been budded. A fresh mellow loam, on a perfectly dry subsoil, is most suitable for the peach and nectarine; and, when planted, the next step of importance is the manner of pruning and training the trees in order to render them healthy and constantly fruitful. In this the utmost skill of the gardener is required; because, as they are to be trained to a wall or trellis, the natural form of the head cannot be allowed; and therefore the natural vigour of a young healthy tree must be so far subdued, that a moderate habit of growth be induced, in order that it may be compelled to be content with a limited space of wall, unnatural form of head, and yet, at the same time, be prolific.

This subduction of the natural vigour can only be accomplished by the manner of training. If all the branches were trained perpendicularly, the growth would be extraordinarily luxuriant, and, if luxuriant, they would be certainly unfruitful; because the growing principle neutralises the productive one—strong shoots, numerous laterals, and large leaves, are produced instead of those of moderate growth, plennished with flowers. To prevent this unfruitful waste of vegetable strength, the branches must be trained out of their natural position; a part of them must be laid horizontally, or even descending, rather than upright, in a sinuous direction rather than directly straight. By these means a moderate motion of the sap is induced, a partial stagnation promoted, and a fruitful rather than a barren habit acquired.

Practitioners have had recourse to different methods of training to accomplish this moderate habit of growth. One is to train the stem quite naked to a considerable height (six or eight feet), and then allowing branches to diverge in all directions over the face of the wall. The distance between the root and the branches being a lengthened course for the sap to be invited or propelled upwards, moderates, and, as some imagine, elaborates it in quality, and therefore fits it to flow into the branches for the purpose of fruitfulness. Others think that a single stem concentrates the current of the sap too much, and therefore advise the stem to be divided into principal arms near the ground, and these trained, first horizontally, and afterwards zig-zagly upwards, allowing lateral secondary branches to be produced and trained right and left from the principals, and whence the bearing shoots of every year are ejected. Another method is to train, radiating upwards, a dozen or more principal branches, and extended as far as there is room, or convenient, they should grow in right lines. These are called *mother-branches*; because a regulated birth of young shoots are annually produced from them, which, being laid in the intervals, yield the flowers and fruit of the next year. This system of training and pruning the peach is much practised in France, and by a few English gardeners, and is highly commended.

The methods generally practised, however, in British gardens, is that called *fan-training*, that is, training a principal part of the leading shoots in all directions from the crown of the root. Young bearing

wood is carefully preserved over every part of the tree, and young branches are ever rising from the lower parts of the tree, to succeed those which have become worn out above.

These trees bear their fruit only on the moderate-sized shoots of the former year; and this is one reason why so much skill is required in their management. Standards in the open ground need no pruning, because the head takes its natural rotund form, and the vigour being distributed into so many channels, it is never redundant in any one place. Standard peach trees are, however, but seldom seen in our gardens, being seldom fruitful unless they stand in very sheltered situations.

PEAR—is the *Pyrus sativa* of De Candolle. A highly-improved garden and orchard fruit-tree. The pear is found wild in England, and probably over all the continent of Europe. In its wild state the fruit is small, hard, and austere; but, since its domestication, new varieties of the greatest excellence have been obtained, vying in flavour even with some of our best peaches, and, in one respect, superior to them, in keeping good for several months after being taken from the tree.

The different varieties are propagated by grafting on stocks raised from the seeds of any of the common sorts, more especially those of vigorous and upright growth. Sometimes quince-stocks are used for particular sorts, especially if the trees are required to be dwarfs.

In gardens the pear is trained on walls, or as espaliers, or trained in the low bush-form on the borders of compartments. Such as are planted as riders on walls, or high standards in orchards, always come into bearing sooner than dwarfs planted in the same places, because the former grow with less vigour.

Crops of pears are frequently lost by reason of their early flowering. Night frosts often occur when the trees are in blossom, and the protruding style of the flower, being remarkably tender, is sure to suffer; and, notwithstanding the hardy character of the tree, the flowers are as easily killed as those of the peach, and require covering quite as much.

The old sorts of the French pears, such as the colmar, cressanne, St. Germain, &c., do best on east or west walls; but the new sorts lately introduced from France and Belgium are found to do well as standards.

Young trees require a longer period of time to come into bearing than most other sorts of fruit-trees. This is discreditable to the gardening world, as assuredly there are practical means by which this defect of the pear-tree might be easily remedied.

PEDALINEÆ. A natural order, containing only one genus, of which there is only a solitary species yet discovered. The plant is a herbaceous annual, found in India; its leaves, when steeped in water, render it viscid, in which state it is recommended to be drunk by patients suffering under dysuria. The *Pedakum nurex* was formerly placed among the *Bignoniaceæ*, but separated on account of the small number of seeds in each cell of the fruit.

PEDICULARIS (Linnæus). A numerous genus of herbaceous perennials, chiefly European. They are placed by Linnæus in his fourteenth class, and in the natural system among the *Scrophularinæ*. In our hardy collections they thrive best in sandy heath-mould, and the choicer sorts should be potted and

kept in frames during winter. They are propagated by seeds.

PEDICULUS (Linnæus). A genus (or more strictly, *Pediculidea*, Leach, a sub-order) of apterous insects, belonging to the order *Anoplura*, Leach, of minute size and parasitic habits, having only six legs, and the abdomen destitute of articulate movable appendages. The mouth is minute, tubular, and placed at the anterior extremity of the head on the under side, in form of a small rostrum, and enclosing an instrument for suction; the tarsi are composed of a single joint nearly as long as the tibia, and terminated by a single claw of considerable size, folding back upon the inside of the tibia, performing the office of a hook. In several of these particulars we find a difference of character between the suctorial *Pediculi* and those species of *Anopluræ* insects which are attached to birds composing the sub-order *Nirmidea* (*Ricinus*, De Geer), and which have the mouth mandibulated, the tarsi articulated, and terminated by two claws of equal size. All these insects were, however, united by Linnæus in the genus *Pediculus*, and by Leach and Latreille in an order which the former named *Anoplura*, and the latter *Parasita*. Some recent German authors have, however, considered these two groups as belonging to different orders, placing the *Pediculidea* amongst the haustellated insects (*Hemiptera epizoica*, Nitzsch), and the *Nirmidea* amongst the mandibulata (*Orthoptera epizoica*, &c.). We prefer, however, retaining these insects in a single order (*Anoplura*), on account of their general similarity in structure, as well as in their parasitic habits; and, therefore, having already noticed the mandibulated species in the article *NIRMVUS*, and detailed in the article *LOUSÆ* the natural history of the haustellated species, we shall here confine ourselves to a notice of the genera of which the family is composed.

a, the common louse; b, magnified; c, one of the legs magnified; d, eggs; e, ditto magnified.

Genus 1. *Pediculus*, Linnæus. Thorax composed of three distinct segments as broad as the abdomen, the legs terminated by a finger and thumb. The common louse (*Pediculus humanus*), and head-louse (*P. cervicalis*), belong to this genus. The former is comparatively rare. The eggs of these insects are called nits, and are attached to the hairs of the body or head. They are provided at one end with a cap which slips off with ease when the young first bursts forth. The males of these two species have the abdomen terminated by a small conical scaly organ.

Genus 2. *Phthirus*, Leach. Body short, rounded, thorax very short and indistinct, the four hind legs very thick, *Pediculus pubis*.

Genus 3. *Hæmatopinus*, Leach. Thorax narrow, distinct; abdomen very broad. The type is the

D D

Pediculus suis, Linnæus, found upon swine; but those found upon the deer, calf, ass, &c., are also referrible to this genus.

PEDILANTHUS (Necker). A genus of curious plants from South America, belonging to *Euphorbiacæ*. The flowers are mostly scarlet, shaped like a slipper (hence called the slipper-plant), and are cultivated in dry soil, being liable to rot if kept moist at the root. They may be increased by cuttings.

PEGASUS. A curiously formed genus of fishes, belonging to the very limited order *Lophobranchii*, or those which have the gills in tufts. There is only one other genus in the order, the genus *Syngnathus*; but it admits of division into three sub-genera. See **SYNGNATHUS**.

The fishes of this order altogether are of no use to man; they are generally of very small size, and have scarcely any flesh upon their bodies; but their singular forms cause them to be much sought after to form part of the museums of those who are more partial to the curious in nature than to the useful.

Singular as the external form of the head is in those fishes, it, nevertheless, consists of exactly the same number and arrangement of bones as in the more regularly formed and typical fishes. They have a projecting muzzle, with the mouth at the underside of the base, and not at the extremity, and this is protractile, something like the mouth of the sturgeon, though the bones are different from those of that fish. The body is covered with scales, which rise into spines on the middle, and have hard ridges at their junctions. The part which contains the cavity of the body is much thicker than in the *Syngnathus*, and it is depressed or flattened; the gills open by a hole on each side; the ventral fins are before the pectorals, which are generally large, and have something of the appearance of wings, which is the reason of the name Pegasus being given to the fishes. The dorsal and anal fins are placed opposite to each other, and the cavity of the body is very short.

There are two or three species all inhabitants of the Indian seas. One of these is called the sea-dragon (*P. draconis*); but though it is a singular looking creature, there is little probability of its having given rise to those fables of dragons which the heated imaginations of the ancients represented as being so terrible. It is a fish of about three inches in length, feeding on little worms and other very small substances, and quite incapable of doing the least harm to any creature of even half its own size. There is some fanciful resemblance to a winged horse in it, from the form and direction of the pectoral fins, and the fact of the ventral ones being in advance, and filaments which give them the appearance of two fore feet. Nor is this little fish altogether without a sort of flight, for when it comes to the surface, it can strike the water with so much force with the pectorals, as to project itself some distance through the air, in a manner similar to that of the flying-fishes. Some of the other species have this power in a still higher degree.

PELARGONIUM (Heritier). An extensive genus of highly ornamental plants, mostly natives of southern Africa. This genus was called geranium by Linnæus, and forms a principal division of the natural order *Geraniacæ*. The genus is divided into twelve sections, with numerous sub-sections, comprising two hundred and thirty-nine species, and two

hundred and sixty-two varieties. These are already named in books; and no doubt there are quite as many more unnamed varieties. The major part of them are easily grown and propagated by cuttings.

PELECINUS (Latreille). A very singular genus of hymenopterous insects, belonging to the section *Pupivora* and family *Evaniidæ*, distinguished by the extraordinary length of the abdomen, which is very slender in the females, and not terminated by an exerted ovipositor; in the males it is long and clavate. There are several species, but nothing is known of their habits. They are confined to America, the type being the *P. polyturator*, Drury (*polycerator*, Latreille), which is entirely of a shining black colour, whence the specific name, and which is not uncommon in the southern states of North America.

PELICAN (*Pelecanus*). A very remarkable genus of web-footed birds, of which the following are the characters: the bill long, straight, broad, and very much flattened; the tip of the upper mandible furnished with a nail in the form of a claw, very much hooked, and exceedingly strong and sharp; the lower mandible consists of two distinct bones, which are a considerable distance from each other for the greater part of their length, but joined at the tip of the mandible. These bones are flexible, and there is attached to them that sac or pouch which is so conspicuous in birds of this genus. This pouch is formed of two membranes, the external one being skin properly so called, and the internal a continuation of the lining of the gullet. This pouch answers nearly the same purposes as the crop or craw does in birds which possess such an organ. The food is taken into the pouch in much larger quantities than the digestive stomach can receive at once; and it is gradually conveyed to that stomach as the process of digestion goes on. The pouch is a mere receptacle containing no fluid capable of digestion, or in any way altering the food. The Chinese and some other nations occasionally turn this property to their personal advantage. The pelicans are most assiduous and successful fishers, and the people alluded to put a ring round the neck of the bird, which prevents it from swallowing, so that they can take the load of fish out of its pouch. This may be done again and again, and the bird still continue to fish; and when they have employed it as much as they wish, they remove the ring and either feed it or allow it to fish for itself. The face and throat of the pelican are naked; the nostrils are long narrow slits at the base of the bill; the legs are rather short, but very stout, and all the four toes are included in the web, in the same manner as in other birds which make use of the foot in rising from the water. They occur in the warm regions of the world rather than the cold. They haunt the rivers, the lakes, and the coasts of the sea. They are excellent swimmers, and, though their flight is wavering in consequence of the lightness of their bodies, they are powerful on the wing. Perhaps the body of the pelican is better supplied with air-sacs and air-tubes in the bones than that of any other bird; and this circumstance makes it rise much more easily from the water than if it were a bird of firmer structure. They do not remain constantly on the waters or their margins, but very often perch on trees, and form their nests there. Their nests are also often formed in those ruins which are so frequent in some of the warmer countries which have been so often conquered and reconquered. In many such places the elevated grounds upon which

those ruins stand have become dry and waste ; and this is the reason why the name of the pelican is so often associated with that of the wilderness. The wilderness would, however, be in itself but a poor pasture for a pelican, for pelicans are among the most ferocious of the feathered race. It may happen, however, that the nest is in a desert place, at some miles' distance from those waters in which the birds seek their food ; but wherever it is situated, there is always sure to be plenty of fish obtainable at no great distance. It is worthy of remark that all the entire web birds which fish over the broad waters, and dart down upon their finny prey, build their nests in lofty places ; but such is the fact, and they evidently do it in order that when they take wing in the morning they may have complete command of their work. Pelicans are birds of large size, their dimensions being about the same as those of the swans ; and their flesh is moderate in quantity, and very hard and nauseous to the taste.

All the known pelicans bear a very strong resemblance to each other ; and, when full-grown, the sexes also are nearly alike ; but the young birds are different, and, as their plumage changes gradually for a year or two, the young of the common pelican have been described by authors as two distinct species.

COMMON PELICAN (*P. onocrotalus*). This species is between five and six feet in length, and about eleven feet in the extent of the wings ; but the legs are comparatively short. The general plumage is white, more or less glossed with a very faint tinge of rose or flesh colour. The pouch under the lower mandible is of bright yellow, loose, membranous, and capable of being greatly distended so as to carry a great load of fish. This bird derives its specific name from the cry it utters, which is most loud when on the wing. The ancients likened this cry to the braying of an ass, and certainly there is some justice in the comparison. The birds are found in Asia, Africa, and South America, whence, about the middle of September, they migrate to Egypt in regular companies, maintaining a uniformity of figure in the air as they proceed on their journey, which figure is broad in the front, and terminates latterly in an obtuse angle. In the summer months they resort to the shores of Greece and the coast of the Black Sea ; and they are also occasionally seen in France ; but they have never been met with on the British shores.

When out on their fishing excursions, they do not consume their prey as they catch it, but fill their pouch and return to shore to enjoy at leisure the fruits of their labour. They are generally seen on these excursions in the morning and evening, these being the times when their prey is most astir ; and, as they very speedily digest their food, they usually fish oftener than once in the course of the day. They are so voracious that a single bird will consume at one meal as many fish as would be sufficient to dine a family of half a dozen people ; and, when pressed by hunger, they do not hesitate in devouring rats and other small mammalia. When night approaches, it retires a little way inland, where, with its head leaning on its breast, it takes its repose, nor does it think of stirring from this posture till the calls of hunger arouse it into renewed activity. It then takes its way seaward, and, raising itself some thirty or forty feet above the surface of the waves, with one eye turned downwards, it continues to float along till it perceives a fish near enough to the surface, when it

descends, with the swiftness and certainty of an arrow shot from the bow of an experienced archer, upon its prey, pouches it up, and again rises to the same altitude to resume the same operation, which it continues till a sufficient quantity of food has been obtained. The young are fed by the female with fish that have been softened for a considerable time in the pouch. The pelican is quite susceptible of domestication ; and it may also be trained, as we have already hinted, to fish in this state with much advantage to its owner. Pelicans and cormorants are said to practise a very singular and ingenious method of fishing in company. They proceed to a considerable distance from the shore, where they spread themselves out in a circle ; the pelicans flap the waters with their wings, and the cormorants dive under the surface, and this operation is continued till the circle is narrowed and the fish contained in it are driven before them towards the land, where they become a comparatively easy prey to their pursuers. In this operation they are usually attended by a number of sea-gulls of various species, which generally come in for a share of the spoil. Marshy and uncultivated places are usually the nesting places of the pelicans, more especially in the vicinity of islands and lakes. The nest is of considerable depth, and about a foot and a half in diameter. It is formed of sedges and other aquatic plants, and lined with the softer grasses. The bird, however, often dispenses with any formally-constructed nest. The eggs, which are generally two in number, are white, of an almost perfect oval form ; and, when the bird is fearful of their being disturbed, it sometimes conceals them under water for a time. When the nest is situated in dry and desert places, the bird conveys water to its young in its capacious pouch, which is capable of containing nearly twenty pints of liquid. The story of its feeding its young with its blood must, however, be classed among the fables of old.

Two or three other pelicans differ so much in colour from this common or most generally distributed one, that they perhaps deserve a separate notice, though it does not appear that there is the slightest shade of difference in their manners. In so far as a deeper and fainter shade of the reddish tint is concerned, no specific distinction may be made ; because this tinge invariably fades, and sometimes goes off altogether, after the birds are dead. This seems to be the case with a species different from the common one, of which some specimens have been obtained from Africa, and therefore it must be referred to the common one. There is an American one, however, which have the bill differently coloured, and an Australian one which has considerably more black in the plumage.

RED-BILLED PELICAN (*P. erythrorhynchus*). This is a native of North America, and is rather smaller than the common white pelican. As in that, its general plumage is white, with the primary quills black, and the hind head furnished with a crest of feathers, four or five inches in length. The bill is of a reddish colour, the upper mandible smooth toward the base, but rough with tubercles in the distal half of its length. The lower mandible is also red, and marked, about the middle of its length, by a round spot upon each side. The pouch is white, and not yellow as in the common pelican, but it is streaked with black lines, and the feet are also black.

SPECTACLE PELICAN (*P. conspicillatus*) is described

as a New Holland species, about the same size as the common one, and, like that, white in the general plumage, but with additional black markings; these are placed on the scapulars, the middle coverts of the wings, and the quills and tail feathers. The lesser coverts of the wings are white, the feathers being long, narrow, and pendent over the wing. A small space round the eye, and also the bill and the pouch, are reddish, and the feet are brown.

A pelican beating on the waters is really a fine sight. At one time it flies close to the surface, and actually strikes the water with its wings, making a splash and causing the body to bound upward every time that it does so. Again, it soars aloft until it perceives a fish, and then it pounces upon that fish, not perhaps with exactly the same splendour as the gannet, but still in a very splendid style.

PELIDNA (so called from the prevailing tawny brown colour of the upper part). A genus of birds belonging to the order *Echassiers*, and comprising the smaller species of birds, allied to the sanderlings, which for the greater part of the year run screaming about those shelving portions of the coast from which the sea retires to some distance at low water. The whole of those birds which are not in the water as waders, or upon it as swimmers, are birds of great interest, and many of them are highly prized as food. But they are very numerous, and we shall be better able to give a short explanation of their coincidences and their differences, by bringing the whole into one article, which we purpose to do in the article *SNIPE*, or snipe family.

PELOPÆUS (Latreille). An interesting genus of aculeate hymenopterous insects, belonging to the tribe *Fossores* and family *Sphegidae*, having the mandibles unprovided internally with teeth, with the second submarginal cells of the anterior wings receiving two recurrent nerves; the clypeus is also dentate, and the maxillary longer than the labial palpi; the abdomen is attached to the thorax by means of a very long and slender footstalk. These insects (none of which are inhabitants of this country, although *P. spirifer*, Linnæus, is a reputed British species) construct their nests, according to Reaumur, in the interior of houses and outhouses. Their nests are composed of kneaded earth, &c., which they fix in the corners of rooms, &c. They are of a rounded form, and consist of a spirally-twisted thread of mould, exhibiting also on the underside two or three rows of holes. The nest is afterwards provisioned with living insects for the supply of the future young, when hatched from the eggs, also deposited at the same time in the nest. M. Palisot de Beauvois, in his splendid work upon the insects of Africa and America, says, that the store of food of *P. spirifer* consists of spiders. The same author adds decidedly, that this species closes the aperture of the cells after the deposition of the eggs. In the first part of the Transactions of the Entomological Society, Mr. Saunders has published an interesting account of the habits of an Indian species of this genus, which are quite at variance with the statements of the French authors quoted above. These insects are exceedingly active; they are generally somewhat more than an inch in length, and of a black colour, varied with yellow. The species are somewhat numerous, and found in all the warm climates of the globe. The best known species is the *Sphæx spirifer* of Linnæus, which is black, with the abdominal peduncle and legs

yellow. It is found in the southern districts of France, &c.

PENEACEÆ. A natural order, containing only one genus, of which there are eight or nine species, all very beautiful greenhouse plants. They have the habit of *Pimelea*, and are nearly allied to *Epacrideæ*. The species grow well on sandy loam and heath-mould, and are propagated by cuttings.

The *Peneaceæ* are evergreen shrubs, natives of southern Africa, with opposite or imbricate, exstipulate leaves, inflorescence terminal, or axillary, the perianth usually of a red hue and inferior. The stamens are definite, either four or eight, exerted from the lower part of the tube of the calyx; the anthers two-celled; the germen is superior, four-celled; style simple; stigmata four. The fruit is capsular and four-celled.

The gum-resin, called *sarcocol*, is the produce of the *Penæa sarcocolla* and other species, natives of Ethiopia. It is an exudation found chiefly on the perianths of the flowers, and, as collected for importation, it is in small grains like sand, of a yellow or reddish colour, and very fragile. Though long known among medical men, and occasionally used as a cathartic, it is now almost forgotten.

PENNISETUM (Richard). A genus of tropical annuals, belonging to the natural order *Gramineæ*, not in cultivation.

PENNYROYAL is the *Mentha pulegium* of Linnæus, an aromatic-scented herb found wild in Britain, but sometimes cultivated as a pot or medicinal herb.

PENTADESMA (Dr. Brown). An African fruit tree, bearing polyadelphous flowers, and belonging to *Guttifera*. *P. butyracea* is the butter or tallow tree of Sierra Leone. The fruit is large, nearly as big as a child's head, and gives out, when cut, an abundance of yellow grease or semi-concrete oil, which the natives mix with their food, but it is not used by the settlers on account of its strong turpentine flavour.

PENTAMERA (Latreille). One of the primary sections into which this author divided the coleopterous order of insects, in consequence of the species of which it is composed possessing five joints in all the tarsi (see *COLEOPTERA*). The families of which this section consists are, according to the system of Latreille, as follows:—

Subsec. 1. *Carnassiers*.

Families, *Cicindelidæ*, *Carabidæ*, with its subfamilies, *Dyticidæ*, and *Gyrinidæ*.

Subsec. 2. *Brachelytra* or *Staphylinidæ*, with its subfamilies.

Subsec. 3. *Serricornes*.

Families, *Duprestidæ*, *Elatridæ*, *Cebionidæ*, *Lampyridæ*, *Melyridæ*, *Cleridæ*, *Platidæ*, and *Lymexylonidæ*.

Subsec. 4. *Clavicornes*.

Families, *Scydmenidæ*, *Histeridæ*, *Sitphidæ*, *Scaphididæ*, *Nitidulidæ*, *Engidæ*, *Dermetidæ*, *Byrrhidæ*, *Heteroceridæ*, and *Elmidæ*.

Subsec. 5. *Palpicornes*.

Families, *Hydrophilidæ*, *Sphærididæ*.

Subsec. 6. *Lamellicornes*, which see for its families.

The majority of these families have already been treated upon in their alphabetical situation in this work.

PENTATOMIDÆ (Leach). An extensive family of hemipterous insects, belonging to the suborder

Heteroptera and section *Geocoris*, or land bugs, and at once distinguished by the length of the upper lip, and the five-jointed antennæ. The details of the mouth of one of these insects having been already figured in the article INSECT (vol. ii. p. 851, fig. 89), we need only refer the reader thereto for a complete illustration of the trophi of this family. The body is generally short, oval, or rounded, or more or less depressed; the tarsi are three-jointed, and the antennæ are filiform. The family is of very considerable extent, and comprises some of the largest and handsomest species of field bugs, as the majority of the Linnæan *Cimices* are called.

The family comprises several principal genera, namely, *Scutellera* (of Lamarck, type of the family *Scutelleriæ*, Laporte), having the scutellum very large and covering the body; *Pentatoma*, Fabricius (type of the *Pentatomides*, Laporte), having the scutellum of moderate size; *Tessera*, Saint-Fargeau, having the antennæ four-jointed; and *Edessa*, Fabricius, having the metasternum porrected. These genera have been greatly cut up by Laporte, Curtis, and Burmeister, into minor groups, which it will be unnecessary here to detail, as they rest chiefly upon minute structural distinctions. Amongst the genera separated from *Pentatoma*, the following, as consisting of British species, ought not to be omitted, namely, *Elia*, having the head considerably elongated, and the antennæ covered at the base; *Cydnus*, with the head large, semicircular, the thorax transverse, almost as broad in front as behind, and the legs very spinose. They are chiefly found upon low herbage, *Cimex bicolor* being the type; *Acanthosoma*, Curtis, having the prosternum porrected, type *Cimex hæmorrhoidalis*; and *Pentatoma*, in which the thorax is much narrowed in front, the sternum not porrected, and the antennæ five-jointed; the joints, however, vary considerably in their relative proportions, and the divisions raised thereupon are considered by Hahn, in his "Wanzenartigen Insekten," as so many genera. In the genus *Pentatoma* there are about twenty British species, amongst which the following, described by Linnæus, are especially noticeable: *Cimex rufipes*, *baccarum*, *juniperinus*, *cæruleus*, *oleraceus*, *prasinus*, &c.

In the larva state they resemble the imago, except in wanting the organs of flight, whilst in the pupa these organs are seen in the shape of rudimental cases lying upon the base of the abdomen, those enclosing the wings being smaller, and lying beneath those which contain the wing covers. These changes are accompanied by a total moulting. In all these states their habits are similar, and they possess the same faculties, except those of flight and reproduction. They feed by suction upon the sap of various plants, or the juices of fruits, whilst some attack other insects, even including weaker individuals of their own species. The greater part emit a most disagreeable odour, which they communicate to whatever they feed upon. The eggs are deposited together upon the leaves or stems of vegetables, being fastened by means of a viscid fluid. They are disposed in regular layers, and we learn from Kirby and Spence that the female sits upon these eggs like a hen brooding over her nest, a peculiarity in insect life which is of exceedingly rare occurrence.

PEPEROMIA (Ruiz and Pavon). A genus of American herbaceous perennials, belonging to *Piperaceæ*. The species are the herbaceous tribe of pepper-bearing plants, the true peppers (*Piper nigrum*,

&c.) being climbing shrubs. They are all tropical plants, abounding in the hottest regions, and exclusively found in the equinoctial zone. They grow very well in our stoves.

PEPPERMINT is the *Mentha piperata* of Linnæus, a British herbaceous plant, belonging to *Labiata*, and cultivated in gardens for the druggist and distiller.

PEPSIS (Fabricius). A genus of hymenopterous insects belonging to the fossorial aculeata, and family *Pompilidæ*, having four submarginal cells, the four palpi of nearly equal length, the two terminal joints of the maxillary and the last joint of the labial palpi being shorter than the preceding joint. The abdominal peduncle is short. These gigantic sand wasps appear to be confined to South America, and far exceed in size any other species of the order to which they belong. They are remarkable for the brilliant velvety colours of the body, which change when held in different positions. Their wings are generally either of a shining blue-black or fiery red. From their great size and energetic activity of motion, it may be easily supposed that the effect produced by their stings is no trifling matter. In their economy it is most probable that they resemble the *Pompilidæ* of our own country.

PERAMELES (literally, "pouched badger"). A genus of marsupial animals peculiar to New Holland. They are animals of slow motion, but they have no resemblance whatever in their structure to those badgers which belong to the common placental mammalia.

The generic characters are chiefly founded upon the teeth, which are the great means of distinguishing the pouched animals from each other; as none of those animals have horns, great differences in the coverings of the body or very great in the structure of the feet, by means of which we could divide them into orders in the same manner as we divide the other mammalia. This genus have forty-eight teeth in all; in the upper jaw there are ten incisors, two canines, six false grinders, and eight true ones; in the lower jaw the number of canines and grinders is the same, but there are only six incisors; the upper incisors are peculiarly formed at the ends, their extremities being bevelled off to a lengthened oval, with the convex or trenchant end outwards; the first one is very small, and inclines inwards, the three following are larger; these, to the number of four on each side, are close together; but there follows an open space between them and the fifth one, which is small; there is also an empty space behind the canine, which tooth is sharp and crooked, compressed laterally; the other teeth are also peculiar in their structure, but the details are tedious, and the more so, that the use of the peculiarities which they present is not known; the head of the animals is long, and the muzzle pointed; the ears are of mean length; the feet have five toes furnished with large and nearly straight claws; the thumb and little toe on the fore feet are sometimes little else than rudimental; the hind feet are considerably longer than the fore ones, and have only four toes upon each; the inner ones are very small, and the first and second are enveloped in the skin as far as the claws; the third one is very stout, and the fourth small; the tail is not prehensile, but soft and velvety, of mean length, pointed, and with some fur on the under side; the covering is of two kinds, a close fur immediately on the skin, and

longer hair projected through it. The females are furnished with the marsupium. This genus are, in a great measure, earth animals, digging passages under the ground, something after the manner of moles, and living upon dead animals, small reptiles, and insects. They are pretty numerous in various parts of New South Wales, where they make their burrows in the dry and sandy ground.

LONG-NOSED POUCHED BADGER (*P. nasuta*). This species has the head very long, and the muzzle drawn out and flexible, and the nose or point of the muzzle extending a good way beyond the mouth; the body is about sixteen inches long, and the tail about six inches more; the ears are short and oblong, and the eyes very small; the fur is pretty thick all over the body, but most abundant on the shoulders and ridge of the back, where the long hairs are also the most plentiful; they are ash-coloured at their origin, and black or fawn-coloured at the points; the mixture of colours makes the whole of the upper part appear, as it were, of a uniform brown; and the under part is white, and the claws are yellowish; the tail is dark brown on the upper side, with a streak of maroon down the middle, and chestnut on the under side.

BOUGAINVILLE'S POUCHED BADGER (*P. Bougainvillei*). Though this has been described as a separate species, and differing in some of its characters from the former, it is highly probable that it is nothing else but the young of the others; but these are obscure creatures in their habitations, and their history is not much known.

FAT-POUCHED BADGER (*P. obesula*). This differs a good deal in form from the other, has the nose short, and the outline of the forehead arched. It is also a much smaller animal, being only about the size of the brown rat; the form of its body is very thick and short; its ears are rather large and rounded, the general colour of the fur is reddish-yellow on the upper part, with black points to the silky feathers, and it is white on the under part; the manners of this one are just as little known as those of the others, because the creatures live lonely, and seldom appear.

PERCH (*Perca*, or rather, perhaps, *Percida*, the perch family). A genus, and also a family of spinous-finned fishes, and remarkably characteristic of that order of the finny tribes. So characteristic are they indeed, that Cuvier has given them the foremost place in his arrangement, and placed the common perch at the head of the family, as a most typical fish. The family contains a vast number, not of genera merely, but of sub-families or groups. There is a sort of general likeness running through all these groups; and yet, in the details of their characters, in their haunts, and in their habits, they differ greatly from each other. Some are of considerable size, others are small; some are armed with spines capable of inflicting very serious wounds, and others have none of the spines capable of inflicting an injury. Some swim in the free waters, others lurk in the mud at the bottom; and there are even some which are capable of journeys, though very short ones, upon land. Some notice will be found of the place of the family in the article FISH; and some of the more singular species are described under their proper names in the order of the alphabet.

The leading divisions of the family are, first, the true perches, *Perca*, which have the ventral fins placed exactly under the pectorals, the gill-lids armed with spines, and the gill-flaps toothed; second, *Cen-*

tropomus, which have the flaps toothed, but the gill-lids without spines; they have often, however, a spine near the orbit of the eye; third, *Enoplosus*, which differ from the second division in the height of the body, and also in the greater production of the dorsal fins; their gill-lids have spines on them, and the flaps are toothed, and also have a few spines; fourth, *Prochilus*, which have only one tooth in the gill-flap; fifth, *Sandat*, which have the flap toothed, but no spines on the lid; their heads are without scales, and their jaws are armed with pointed teeth; sixth, *Tetraodon*, having the body and head oblong, the muzzle blunt, the scales minute, and the body small, and with even rows of teeth. Fishes of this sixth division are very abundant in many latitudes, and very easily caught. The master fishers of those latitudes feed their slaves with the flesh of these fishes, which, though not very palatable, yet can be eaten; and this is the reason of the name *Tetraodon* being given to them, which, we believe, is the Japanese for slave's meat; seventh, *Apogon*, the fishes of this division make a very close approach to the mullets, but they can hardly be considered as true perches in any but the first of these divisions; to it, therefore, we shall restrict the remainder of our observations.

THE COMMON PERCH (*P. fluviatilis*), is the typical species of the genus; and it is a fish with which every one who knows anything about the fishes of the still fresh waters of Britain must be well acquainted.

The characters of the genus are: two dorsal fins, separated from each other by a smooth space, the first having spinous rays, and the second flexible ones; both jaws, the front of the vomer and the palatal bones are armed with teeth; the tongue is smooth; the gill-lid is bony, and terminates in a flattened point; the under gill-flap is toothed behind, and has a notch below; there are seven rays in the gills, and the scales are rough and hard, and not easily detached from the skin. The common perch is found in the lakes, large ponds, and other currentless waters of all Europe, and the corresponding latitudes of Asia. There is some reason to believe that it agrees better with cold latitudes than with those which are warmer; for perches, three or four feet long, are mentioned as being taken in Sweden and Lapland; whereas in Britain or in France, they rarely exceed a foot and a half. Specimens larger still are mentioned as occurring in some parts of Siberia; but they leave some room for doubt. The perch has been known in all ages, as well as in all countries whose story in the history of civilised man is of any considerable length. The Greeks and Romans were well acquainted with it, and described it accurately; and it is not a little remarkable, that in most countries in Europe, its name differs very little from the specific one given to it by Aristotle. Few lakes or large ponds in Britain are without perch, and as they are exceedingly bold and voracious, they are very easily captured. We shall quote Mr. Yarrell's accurate description of its appearance. "The perch," says Mr. Y., "though very common, is one of the most beautiful of our fresh-water fishes, and when in good condition, its colours are brilliant and striking. The upper part of the body is a rich greenish-brown, passing into golden yellowish-white below; the sides ornamented with from five to seven dark transverse bands; the irides golden yellow; the first dorsal fin brown, the membrane connecting two or three of the

first and last rays spotted with black; the second dorsal and pectoral fins pale brown; ventral, anal, and caudal fins bright vermilion. A deformed variety of perch, with the back greatly elevated and the tail distorted, has been noticed by Linnæus as occurring at Fahlun in Sweden, and in other lakes in the north of Europe. Similar perch are also found in Llyn Raithlyn in Merionethshire. A fish of this description is figured in the volume of Daniel's Rural Sports, devoted to Fishing and Shooting, page 247. Specimens of the perch, almost entirely white, have also been found in the waters of particular soils."

Perches can swim with great rapidity, and they often associate together in considerable troops. In fine tranquil weather these troops may be observed in a lake, a river, or even a large ditch, drawn up in lines with all the regularity of an army near the surface of the water, and perfectly motionless. But their perceptions are very keen; for the least disturbance of the state of things around, sets the whole instantly off with wonderful celerity; and even when one who is observing them is aware of nothing calculated to give alarm, they will dart off as if an electric shock were discharged into the whole.

Perches are exceedingly voracious. Their common food consists of tadpoles, water-newts, frogs, and other reptiles, and also of worms, molluscous animals, and small fishes. It is alleged that they sometimes pay rather dearly for their fish dinners, for they sometimes swallow the stickleback, the strongest spines of which fasten in the gullet, so that the perch can neither get it up or down, and consequently it is starved to death. The strong spines in the dorsal fin of the perch sometimes make it a very unpleasant mouthful for its still more ravenous neighbour the pike; and sometimes when the perch has been actually seized, the pike may be seen to shake it out again, apparently in great pain. There is one enemy, however, against which the perch has no defence. This is a little feeble crustaceous animal of the genus *Cymothoe*, which enters the mouth of the fish along with the water, and preys upon the substance of the gills. The gills of every fish are the most susceptible parts of it; and we need not wonder that a perch, which has perhaps hundreds of these little creatures eating away at its gills at the same time, must suffer the greatest agony that can be inflicted on a fish.

It is generally understood that perch are not fertile till the third year. They spawn in April or May, according to the season and climate, and they are very prolific. The eggs are usually deposited among aquatic plants, such as the stems of reeds and rushes. They are not buried in beds like the eggs of the salmon, but united to each other in a species of little strings. Bloch mentions three hundred thousand eggs being found in a perch only half a pound weight, and more than three times the number in one of a pound weight. The perch is tenacious of life, and may be carried in wet grass for a pretty long distance, so that nothing is easier than to stock any suitable water with perches.

PERESKIA (Haworth). A genus of West Indian fruit-bearing shrubs, commonly called the Barbadoes gooseberry. This genus was named *Cactus* by Linnæus, and it is still kept in the order *Opuntiacæ* or *Cactææ*. It differs from the other *Cacti* in having more of a ramified and shrubby appearance, as well as a hostile character, being profusely armed

with spines. The fruit is about the size of a small plum, and very pleasant to eat. They are perfectly easy of increase by cuttings; and they make an excellent stock on which to work the other *Cacti*, particularly the *Cereus truncatus*, which, growing from an elevated stem of a pereskia, is a beautiful ornament.

PERGULARIA (Linnæus). A genus of tropical climbing shrubs, bearing curious pentandrous flowers, and belonging to *Asclepiadææ*. It is easily cultivated, and the flowers are highly valued for their fragrance.

PERIPLOCA (Linnæus). A genus of deciduous and evergreen climbing shrubs, belonging to the natural order *Asclepiadææ*. Three of the species are from the south of Europe, and one is found in India. The *P. græca* is a common bower plant in our gardens, and, like the others, is propagated by layers.

PERIPTERA (De Candolle). A curious flowering evergreen shrub from New Spain, belonging to *Malvaceæ*. From the remarkable shape of the flowers it is called the crimson shuttlecock. It succeeds in our stoves, and is increased by cuttings rooted in the usual way.

PERIWINKLE is the *Vinca minor* of Linnæus, which, with several other species, are frequent in our flower borders; and an Indian sort, *V. rosea*, is common in our hothouses. They belong to *Apocynææ*.

PERLIDÆ (Leach). A family of neuropterous insects, belonging to the tribe *Filicornes*, and distinguished by having three joints in the tarsi; the mandibles small and membranous; the posterior wings larger than the superior, and folded on the abdominal margin when at rest; the body is long, narrow, and flattened, and the wings, when the insects are not in the act of flying, are carried flatly upon the back; the abdomen is generally terminated by two filiform threads. These insects frequent the neighbourhood of water, and are very inactive; they are especial favourites with the trout, and imitations of some of them are amongst the most "killing flies" in the fly-fisher's entomology. The larva, as we have long been aware, is an active insect which resides in the water without any cases, although the contrary is expressly stated by Latreille. A figure of one of these larvæ has been published in the German periodical, *Der Naturforscher*, full half a century ago; and yet, from ignorance of this fact, and the assertion that the larvæ reside in cases like the caddice worms, the greatest confusion has been made by those authors who have attempted to arrange the *Neuroptera* in a natural system. The type of the family is the *Perla bicaudata*, the specific name of which, however (two-tailed), indicates a generic character. It is not very common. There are other species of the genus, the males of which have very short wings; others, which differ only in having wings of equal size in both sexes, form the genus *Isogenus* of Newman. *Nemoura* of Latreille is generically distinguished by having no filiform appendages at the extremity of the abdomen. There are many species of this genus which depart from the habit of the family by being generally found in damp woods. Some other genera have been described by Mr. Stephens in his Illustrations of British Entomology, together with descriptions of all the species.

PERSEA (Gærtner). A fruit tree called, in the West Indies, the alligator-pear. It belongs to *Laurinææ*, and was formerly called *Laurus persea*. It is propagated by layers.

PERSICA (Tournefort). A genus of fruit trees

said to be natives of Persia, containing only two species, or in fact only one; for making the nectarine a species is a piece of ridiculous discrimination. See PEACH.

PETAURUS. A genus of marsupial mammalia, natives of New Holland, and called, by the English settlers there, flying cats, flying foxes, flying squirrels, or any thing else in the mammalia of Europe to which they were fancied to have the greatest resemblance. By many naturalists, or at all events many authors, they were at first confounded with the opossums, to which, however, they have little or no resemblance. They are wholly confined to New Holland and the adjacent isles; and they are invariably tree animals. None of them can exercise any function entitled in the slightest degree to the name of flying; but they have some cross motion of the legs, and the power of extending between them a loose fold of the skin of the sides, which forms a very efficient parachute. The most remarkable characters of the genus are the following: in the upper jaw there are six incisors, and, generally speaking, no canines, though the presence or the absence of these is not a constant matter; the cheek teeth in this jaw are sometimes six, and sometimes seven; in the under jaw there are two incisors, the canines are generally wanting, and the number of cheek teeth is not determined; the intermaxillary bones of the upper jaw form an angle with each other; the incisors are large in the front, and have powerful cutting edges, but get gradually smaller as they proceed backwards; there is a blank space between the incisors and the false grinders; the first false grinder is very small, the second a little larger, and the third larger still, and having its crown formed something like that of a true grinder. This structure of mouth is rather an anomaly, when we come to compare it with the mouths of the ordinary mammalia in which each is tolerably constant to the general type belonging to its order. It is not a decidedly carnivorous mouth certainly, and perhaps the nearest approach to it is found in the mouths of the rodentia; but still it cannot be considered as identical with these. They live, as we have said, in trees, and repose chiefly during the day, so that if not absolutely nocturnal, the morning and evening appear to be the chief times at which they are active. They leap from branch to branch with great adroitness, and are among the most numerous mammalia to be met with as natives of Australia. The aboriginal inhabitants of that island seek after them with great assiduity, and smoke them out of the hollow trees by fire. The head is long, the ears large, the eyes also are large, and the nose pointed, and the naked part of it covered with that peculiar but almost indescribable sort of skin which never fails to point out that any animal upon which it is seen is marsupial. The legs are short but stout, and all the feet have five toes; the inner toes upon the hind feet are placed considerably farther back than the others, and without any nail; it is probable that they act as points of support in grasping; the first and second toes upon the same feet are rather shorter than the others, and partially united by membrane; all the toes on the fore feet are free, but the inner ones, or those answering to the thumbs of hands, are much shorter than the others. The claws are crooked, compressed laterally, sharp pointed, and very strong; and there is no doubt that these animals can seize and retain their hold on a

tree in a very perfect manner. The parachute, which is a sort of mantle, folds into plaits when the fore and hind feet are brought near to each other; but when these are advanced in front and projected to the rear, a large volume of membrane is spread out to break the fall of the animal. The tail is, generally speaking, very long, covered with shaggy hair, and capable of a good deal of motion, but not prehensile. Sometimes it is round in the section, and sometimes flat. They do not appear to be absolutely confined to New Holland; for some are understood to be met with on Norfolk Island, though there is no mention of them in any place more remote from the Australian coasts.

We shall not make use of any general English name for the different species of these animals, but shall speak of them by the epithet only.

The Dwarf (P. pygmaeus). This is a very pretty little creature, about the size of a mouse, but stoutly made; the upper parts are of a delicate mouse-coloured grey, with a reddish tinge, and some clear brown round the eyes; the upper lip and the under part of the body, and also of the expansile membranes, is pure white; the tail, which is long, is a very beautiful organ. It consists of a central articulated part, and an exceedingly regular appendage of reddish grey hairs on each side ranged with the most perfect symmetry, and the whole bearing some resemblance to a handsome little feather; the loose membrane is not attached to the fore feet any further than the elbow joints. Its manners are very little known; and, indeed, it is so little a creature, and so clever among the twigs and leaves of the trees, that it cannot be observed without the utmost difficulty.

The Great (P. maximus). Even this species would not be very great in most groups of mammalia, but still it is entitled to the epithet as compared with the one last mentioned. The body measures altogether about twenty inches in length, and the tail about eighteen; the head is small and the mouth very small, the muzzle being pointed; the eyes are rather large, and, as is the case with the greater number of marsupial animals, they have no appearance of eyebrows or any enfacement in the head; the lines on which they close are very much inclined downwards at their extremities next the nose, and this of itself gives a sinister look to the animals; the ears are large, partially rounded off at their extremities, and they stand nearly at right angles to the mesial line; the tail is very thick of fur, which lies in all directions, cannot easily be ruffled, and thus has a fine appearance; the upper part is, generally speaking, greyish-brown of nearly uniform tint; but it is subject to varieties of colour, and some are met with almost white; the head is rather deeper greyish-brown, with a trace of yellowish-fawn colour down the middle; the throat, the under part generally, and a line on the inner surface of each of the fore legs, are white; the feet are blackish-brown; the tail is fawn colour at the base, increasing gradually to very dark blackish-brown towards the extremity.

Black Petaurus (P. Taguanoides). Though the preceding species is called the great, yet the present is still greater, and this is an instance of the absurdity of giving superlative names to species when little is known of the genus. From this foolish custom, we have some species of plants standing in the list as grandiflora, though the flowers are not half the size

of some others of the genus ; and in other genera we have *gloriosa* and *superba*, applied to the very plainest species of the whole. Though the present species is styled black, it is subject to great varieties of colour, consisting chiefly of various shades of brown and fawn colour, or a clouded mixture of the two ; and some specimens are entirely white. The length of the body is about eighteen inches, and the tail about twenty ; the muzzle is triangular and very pointed ; the ears are large and erected ; the tail is round and very thickly covered with fur ; the fur on the body of the animal is long and close, and remarkably soft, so that it is held in considerable estimation by the furriers ; and we believe that in Sydney it is used in the manufacture of hats. Like the others, it is found in the forests of eucalyptus, in the hollows of which it takes up its abode.

Large-tailed Petaurus (P. macrourus). This species is about the size of a brown rat. The fur on the upper part is brownish-grey, with a dark brown band down the middle of the forehead ; the ears are large, rounded, and of a whitish colour. Like the other, it is subject to very considerable varieties of colour.

Several more species of these animals have been mentioned ; but as this has often been done by rival naturalists, each of whom was more anxious to discover and name a species, than to find out the habits of the species already known, those specific distinctions are really of very little value. In the case of this, and indeed of all the native mammalia of New Holland, the lovers of nature have much to regret. Of all animals they are the most singular ; but the greater part of them are the most obscure in their habits, and, therefore, the most difficult to study. The description of characters that have been sent from Britain to New Holland, to labour in the forests as a sort of penalty for crimes committed in the mother country, are exactly such as we might expect to destroy every living creature that comes in their way, without paying the least attention to its manners. In consequence of this, the native mammalia have been exterminated from all the cleared lands of the colonies, and as it does not appear that any of them, with the exception perhaps of the great kangaroo, have the slightest tendency to be social, there is little chance of their again returning, even when ornamental plantings shall have in part covered and sheltered those grounds which have been so indiscriminately denuded by the desolating zeal of the axe.

This is the master vice or folly of British colonists in every wooded country of which they take possession, and they thereby spoil both the natural history and the land. It will readily be understood, that if a country is thickly covered with a primeval forest, every native creature that lives in it must be adapted to that forest, and form part of the system alone. Consequently, if the forest is suddenly cut down, there is no resting-place or shelter left for the tenants of the forest, and they must either fit before the axe, be killed by the woodsmen, or perish on the clear grounds. This is true, not only of the irrational animals, but of the human natives. Let any one consider how many nations of American Indians have even now their memorial in an historic name, and how speedily the remainder is wasting away before the progress of colonisation by Europeans and their descendants ; and he will once admit that, in as far as the system of nature is concerned, this plan of colo-

nisation is not altogether an unmixed good. It so happens too, that the lands, tender from being so long shaded by the forest, are over-worked in a few years, and thus cultivation cuts down stately trees in order that their place may be occupied by weeds.

PETREL. A family of long-winged web-footed birds, the characteristic family of those which are habitually on the wing on the waters, and may be said to inhabit the wide oceans in the full extent of their breadth. The name petrel has been given to them rather superstitiously. It is a corruption of *Petrellus*, or little Peter, and was given to them because they appear to walk naturally upon the waters, as the Apostle Peter tried to do without very notable success. There are other superstitions connected with them, or at least with some of their species, to which we shall afterwards have occasion to allude, and altogether they are among the most singular and the most interesting productions of nature, not for their commercial value certainly, for that is but small, though there are some of the northern countries in which they are used both as fuel and as candles ; but to one who wishes to understand the system of nature, and see how all parts work together, they have an interest far higher than any mere commercial one. Nor must it be supposed that those enlarged views of Nature's operations on the great scale are contrary to the genuine spirit of commerce, industry, and the multiplication of the comforts of life ; for not only are they the very reverse of this, but they are the very subjects in which commerce originates, and to which all its improvements are owing. Look at the productions of America, North and South, and think what Europe, and Britain especially, would be without them, and then turn round and think by yourself how we came by the original knowledge of these things ? The answer to the inquiry is down upon the record, and never can be obliterated. Columbus crossed the Atlantic. Another might have done this it will be said, to which the answer is, another did not do it. We all know the story of Columbus breaking the egg, when he himself was told that others might have done the same as he did. " Any one can do what I have done, after I have shown them the way," was the implied declaration of the philosophic and enterprising navigator. What led Columbus to propose this enterprise—and he proposed it to several countries, and to England among the rest, before any one would enter into his views to the extent of that humble equipment which he required ? Columbus had studied with the utmost attention the descriptive and the physical geography of the globe as far as it was then known, and he reasoned that if India and China, which were then the most desirable spots, could not be reached by a western voyage, more direct than the eastern one, and having the advantage of the trade wind in its favour, the obstacle must be land, and that land an addition to the then known world. This was the general view ; and when the opportunity came, the execution was shaped accordingly. But even Columbus was under no small obligations to the petrels. When hope had gone down to all his crew, who were not supported by the same general views as himself, when they were in a state of mutiny, and Columbus himself would have despaired, if despair had formed any part of his nature, petrels from the gulf weed alighted on the rigging, and produced a similar effect on the crew of the vessel, to that which the dove with the olive-branch is said to have produced

upon Noah and his family. Had it not been for the timely visit of those birds, Columbus might have been flung in the sea, and the vessel might have returned or have been wrecked. America might have remained undiscovered, and the darkness of the middle ages might have been brooding over Europe up to the present hour.

If there were nothing in the history of the petrels but this part which they had in the discovery of America, they would have been entitled to rank high among the feathered race. But their own history is a highly important one. They are perhaps the most numerous of the feathered tribes in individuals, though not in species; and they are dispersed over every known sea, being, in fact, the grand scavengers of the surface of that mighty element. The other long-winged and web-footed birds, no doubt, also ply the same trade; but they are comparatively local in their vocation. The greater number of them are on or near the shores; and though there are some, and those very large and splendid ones, which are discursive over the broad waters, yet they are confined to particular latitudes, and none of them are so seaward as some of the petrels. Petrels are of various sizes and of different habits, and as such they are adapted to different situations upon the waters—the north and south.

The larger ones are accumulated in greatest numbers in the cold latitudes both of the northern hemisphere and the southern. In summer they extend to the very highest latitudes which man has been able to reach on the sea, and should there be clear water at either of the poles, which is not unlikely, as the poles do not appear to be the points of greatest cold, it is probable that numbers may seasonally visit the poles themselves. They are much more abundant in the southern hemisphere than in the northern; and we might expect this, because there is a greater extent of sea in the south, and it is on the sea chiefly that they depend. Some of the southern ones are much larger than the northern; but we are not very well acquainted with the birds frequenting the borders of the southern ice, for those borders are so extensive that it is scarcely possible to explore them. We do not even know what land there may be within those regions to furnish nesting places for those birds which consume the surface refuse of the sea there.

We say consume the surface refuse, because this appears to be the special office of the petrels; and we find their numbers are always great in proportion to the work which they have to do, and their boldness and voracity are in proportion. Taking the whole family, they may be said to be among the most omnivorous birds, eating indiscriminately dead carcasses that happen to be floating, fishes when they can catch them, molluscous animals, and, in short, every animal product of the sea, whether living or dead, so that they can master it.

In the middle latitudes, that is from the centre of the one temperate zone to the centre of the other, their appearance and also their habits are a little different. This does not arise from the sea being less productive in those regions than in the regions of the poles; but the polar oceans are the great eddies of the grand ocean currents, to which no small quantity of the lighter products of the intermediate oceans are carried. Thus, for instance, a great deal of the produce of the American seas, from Davis' Strait south to the extremity of the West Indian seas,

is carried along the margin of the polar ice by the current of the Atlantic, which is indicated by the gulf stream on the American shores. There is even a great deal of the waste of the northern lands carried annually down into those northern seas. The storms of winter destroy many birds and small mammalia, which are carried down to the sea during the thaws and freshes in the spring. These of course go to feed the scavenger-birds of the sea, though, as the gulls are somewhat less seaward than the petrels, the greater share of this refuse of the land falls to them. Dead seals form a considerable portion of the food of the larger petrels. Those seals congregate in immense numbers at their favourite stations, which are generally those where a current along a coast, through a strait or round an island, brings plenty of food for fishes, and consequently plenty of fishes to feed the seals. These seals, when their numbers are not kept down by incessant fishing, are subject to periodical maladies which carry off great numbers of them—numbers so great indeed that, if a long and severe storm ensues, their dead bodies cover the beaches of coasts at a considerable distance from their natural habitations when alive. This mortality among the seals is of course a feasting time with the petrels, the points of whose bills are so formed that they cut like pincers, and very speedily tear the toughest carcasses to pieces. The whale and seal fishings are also times of plenty to the petrels of the neighbourhood; and, though the refuse which is left upon these occasions attracts several others of the sea scavengers, the petrels are by far the most numerous, and the most daring in attempting indiscriminately to seize every eatable substance. In consequence of this, the cutting up of a whale is a scene of great bustle and activity; as it is rather unpleasant work though profitable, the sailors flense off the blubber as speedily as they can, and as that is the time of the profit of the voyage, in which they all partake more or less, they are in high glee. The birds too sometimes almost darken the air, keep up an incessant coil of squeaking and screaming, and ever and anon commit petty larceny upon pieces of the blubber. If one gets a piece, others are sure to attack him, and others these again, upon which occasions they battle with great and very often with fatal desperation. When they are killed, however, the dead bodies of their fellows is just as welcome food for the survivors as any other animal matter. When, owing to any of these causes, the petrels get an extraordinary share of oily food, whether of the whale or seal families, or of any others, they get exceedingly fat; but the fat of them is then offensively rancid, and even the flesh is not eatable by any one who can procure other food. We believe that the same process which the northern islanders resort to for purifying the flesh of many sea birds would succeed with the petrels even at this season; and, if it could be carried into execution, these birds might furnish an abundant supply of fresh provisions. The plan is to clean and skin the birds, carefully remove all the fat, both external and internal, and then bury the flesh in fresh sweet vegetable mould for a day and night or more.

When the petrels are left to the ordinary produce of the sea, their flesh is not so rancid, and the sailors often boil them down into a kind of soup. They are best on the currents, where their food may be supposed to be more miscellaneous than when numbers are attracted to a particular spot, by what may be

considered as an unnatural accumulation of garbage. It is astonishing how soon and with what certainty garbage attracts all the scavenger-birds of the sea. Thus, for instance, if there is a cleanly town upon the shore and a fishing village at a little distance from it, which is in general not remarkable for the cleanness of the beach, gulls are almost constantly to be seen parading about the village as if they formed part of the establishment, while not a single gull visits the town.

The sea and those birds which are specially charged with the office of keeping the surface of the sea clean are very extensive subjects, however, and we can afford room for no more general remarks, though the subject is worthy, and well calculated to repay, the closest attention that can be bestowed upon it.

Petrels admit of subdivision into at least two genera—*Procellaria*, or the larger petrels, which, as we have said, congregate most plentifully in the Polar Seas; and *Thalassidroma*, or those birds of smaller size, and something of a swallow-like aspect, which career more at large over the broad waters in warm latitudes. In common English, the first are called "Petrels," and the second "Storm Petrels;" but the generic names which have been given to them, have almost the reverse meanings. *Procellaria* is formed from the Latin word *procella*, which means a storm, or a bustle and disturbance of almost any sort; and certainly, when the petrels are contending for the krang of a whale, or any other great prize, they make no small *procella* among themselves. The other generic name is more happy, because it is more descriptive of the general habits of the birds. *Thalassidroma* literally means that which courses, drives, or careers over the surface of the sea; and this is the general habit of the storm petrels, though they frequently do alight upon ships, and surround them with plaintive cries, especially on dark nights during storms, when the little creatures have been fatigued by the fury of the wind, and can find no rest upon the tumbling surface of the angry sea.

The genus *Procellaria* perhaps admits with propriety of a further division; for though the birds inhabit the same seas, and carry on the same kind of trade, they do not do it exactly in the same manner. This subdivision consists in separating, from the petrels properly so called, those which are termed puffing petrels; and there is sufficient difference in the structure of the bill, and the habit of the birds upon the waters, to warrant this. The puffins, or members of the genus *puffinus*, resemble the true petrels much more than they do the storm petrels, but still they are intermediate between, and may be considered as more seaward birds than the petrels, and less so than the storm petrels. We shall briefly advert to those three genera as making up the family, and mention one or two of the species in each. To enumerate them all would far exceed our limits—their manners are so much the same that it would involve much repetition, and very little is known respecting many of them, especially those of the Antarctic Ocean.

PROCELLARIA, or petrels properly so called. The characters of these are—the bill about the same length as the head, and very strongly formed; depressed at the base, but having that part fortified by a horny tube, which contains the nostrils. The fact of the opening of this tube being single, is one of the characteristic distinctions between a petrel and a puffin;

but it does not appear to be a very important one, though the two tubes of the puffins may enable them better to resist the entrance of the water, to which they are more exposed than the others, in consequence of their flying lower. A considerable portion of the bill toward the base is straight, but the tip is arched, forming a long, strong, and most efficient nail or claw, with very short trenchant edges, between which the tip of the under mandible is received. This mandible is not bent downwards, but it is so formed as that it slides against the nail of the upper one with a very powerful cutting motion. Both mandibles have also strong cutting edges, so that any ordinary substance can be divided by their entire length. The wings are long and pointed, the first quill being the longest, though they are perhaps not quite so long in proportion as those of the other genera. We shall, however, notice the remaining characters in describing the only species which frequents the British seas, because as the others appear to differ from it in little else than size and colour, this will save repetition.

The *Fulmar Petrel* (*P. glacialis*). This is the petrel, *par excellence*, of the Northern Ocean, and the one which attends so closely upon the northern whale ships. It also appears in great numbers on those parts of the coast which are favourable for its nesting in such numbers, and it drives about so much wherever it is seen, that it has got a vast number of names, such as "Mollmuck," "Mollduck," "John Down," and a number of others. The general colour is whitish, and inclining to hoary on the back. The wings have a dusky shade, and the head and under part of the body are nearly white. The straight part of the bill, and also the nasal tube, which, though it has but one opening at the extremity, contains two distinct nostrils, are brown, and the nail on the tip of the instrument is yellowish. The inner side of this nail is toothed as well as grooved, so that it can take a firmer hold than probably can be taken by the bill of any other bird whatever. The legs are dusky, and the irides of the eyes are yellow. Thus this powerful scavenger of the sea is clad in but homely attire. The colour is, however, subject to considerable variation, which renders it by no means unlikely that those darker specimens which have been brought from the same seas, and have had names given to them as species, were nothing more than coloured varieties of the fulmar.

In the present state of our knowledge, therefore, we are to consider the fulmar petrel as the only true petrel of the north; and its distinguishing characters are, that it remains more within its locality, builds higher, flies higher, and is perhaps a more daring bird than any of the puffins of the same sea. In the Southern Ocean there is a bird very like this, but whether exactly the same or not it is impossible to say, for the species of petrels are so numerous there, that one out of the number is little or nothing.

The flights of fulmars, which are sometimes seen in very high latitudes, are exceedingly great. When Captain Ross made his first voyage to that part of the world, he was detained by the ice for about ten days, in about 71° north latitude. During those days a stream of fulmars continued setting northward over the vessel, unequalled by any known flight, except that of the ash-coloured puffins in Bass's Strait, between New Holland and Van Diemen's Island, or that of the passenger pigeons in the great valley of

America. There is little doubt that this movement north was toward the nesting place of the birds; though whether they nestle there in rocks or on the ice it is not easy to say. The direction which the birds took, and the numbers of them when taken together, afford, however, a pretty strong collateral proof of the fact of there being open water near the pole, and beyond the extreme cold experienced by the navigators, which does not appear to be in a much higher latitude than that in which Captain Ross saw the fulmar, if indeed it is as high.

The fulmar builds in all the northern countries which have been visited—in Spitzbergen, in Greenland, in Iceland, and a few, it is said, in St. Kilda, though the petrel which is so plentiful there, is probably one of the puffins. The fulmars never appear on the southerly coasts of the British Islands, and but rarely on the northerly, for it is only in very severe winters that anything more than a mere sprinkling of them reaches Orkney and Shetland. The nest contains only one egg, as is the case with many sea birds; and it is curious that those birds which have such small broods are yet far more numerous than birds that have larger ones. Besides being eaten by the sailors occasionally, or under particular circumstances, these birds are eaten by the inhabitants of the remote and cold islands; and it is said that in St. Kilda they are salted for winter provision, indiscriminately with other birds. The oil is understood to be previously extracted, and this oil is much prized by the simple inhabitants of that lonely isle. They have not the benefit, such as it is, of reading the marvellous lists of infallible quack medicines which pollute the columns of the newspapers, and tend to set the cupidity of their proprietors over their boasted zeal for the interests and morals of the people. But still fulmar's oil is in St. Kilda what Morison's pills, or anything more famous and filthy, can be in England; and it has the advantage that nobody can be poisoned by it, by what bungler soever it may be administered. A young bird will yield nearly an English pint of this oil, which is beautifully clear if kept above the temperature of fifty-two degrees of the common thermometer, but if it be allowed to get cooler than this it becomes turbid, and when once it does so it is not easily cleared again.

We may add, that the great fishing on the bank of Newfoundland affords a rich time for the fulmar, which greedily devours the offal of the cod as it is thrown from the fishing-boats. In these places, or, indeed, in any place where it hovers in expectancy of food, the bird is easily caught with a baited hook cast on the water, or swung in the air, for it is sufficiently bold to approach within the length of a very short line. When we consider its numbers, its activity, and the fact of its being the only far sea scavenger of the Arctic Ocean, this is one of the most interesting birds of the north.

When we turn our attention to the south, we find the importance of any one species of petrel lost in the numbers of the species; and we find them approaching gradually in size and in some other respects to the large long-winged sea birds which are met with there. Generally speaking, those birds of the south have more colour in their plumage than the fulmars; and perhaps we might expect this, as they occur in a lower latitude, and we find the fulmar paler in the extreme north and sometimes white. It is not easy to determine in every case, without a new examination, whether these birds are petrels or puffins; be-

cause the difference is more in the manners of the birds than even in their structure.

Gigantic Petrel (*P. gigantea*). This is the largest species which is known, specimens being met measuring forty inches in length, and about twice as much in the spread of the wings. The upper parts are whitish mottled with brown. The scapulars, the coverts of the wings, the quills and the tail feathers are brown, with paler margins. The sides and front of the neck, and all the under parts are white; the top of the head is blackish brown; the feet are yellowish grey with black webs; and the bill is brownish yellow, with a very large and strong yellow nail. This species is found only in the Antarctic Ocean, and may, perhaps, be considered as one of the mock typical species there.

Most of the other petrels of the Antarctic Sea are much smaller birds, generally about eight or ten inches in length; and they appear to differ from each other in little else than size and colour. One might be prepared to expect that they should be more discursive birds than the petrel of the north, because there is an uninterrupted sea in their latitudes all the year round; and thus the same bird can freely circumnavigate all the globe. Where many of them nestle is quite unknown, and indeed we are nearly in the same state with the northern ones, for we do not know where those immense flocks which proceed northward in the summer find their nesting places. A good many nestle in Terra del Fuego, the Falkland Islands, Georgia Island, to the south-east of these, and South Shetland, to the south-west of Cape Horn. But as they come seasonably into temperate latitudes, in every longitude of the South Sea, we may naturally suppose that there are nesting places for them all round. The ice, however, will do for this purpose; because a hole in the ice, while it remains without melting, may make a very warm nest, and there is no want of feathers wherewith to line the bottom. In the north we know that there are some birds which do place their nest on the ice; and this may be more general in the south. It is highly probable that, if attention were paid to the motions of these and other birds of the Antarctic regions, with due care, and in the proper spirit of philosophy, without any preconceived theory to trammel the mind, we might be put in possession of some means of at least guessing rationally at what may lie within those icy barriers of the southern sea, which exclude us from actual observation.

The flight of birds, when they are numerous from any particular direction, or to any particular direction, is always a matter worth attending to. The ancients saw this; but the low state of their knowledge unfitted them from making the proper use of it; and as people always do in such cases, they perverted it for superstitious purposes, and sought for a foreknowledge of the fate of human beings, from that which was simply an indication of what had previously happened in some country or another. Whence they come, and why, are the only two questions to which the flight of birds can give any answer; but the rapidity of their motions, and the length of distance for which they can come, render them both early and valuable messengers, if we would but take the trouble of making ourselves understood.

Several species of petrels are mentioned as occurring habitually at intermediate latitudes, such as about New Holland, and some of the groups of

islands in the Pacific; but it is probable that these are puffins rather than petrels, or, at all events, that they have the habits of puffins.

PUFFINUS. The puffins have the bill rather longer in proportion than the petrels, but not so stout, and slightly curved from the base, with both mandibles of an equal length, and both curved at the extremity. The upper mandible is still furnished with a strong nail, and the bill is rather a powerful one, but it is not fitted for such hard work as that of the petrels. The nostrils are in a double tube on the upper mandible, or, perhaps, rather the external tube which surrounds the two tubular nostrils in the petrels, is wanting. The birds also build their nests much lower down, many of them in holes in the sandy islands; and some have the tarsi longer and more slender than the petrels, and can walk better. At sea their flight is more on a level, and nearer the surface than that of the others. They appear to follow the shoals of fishes, especially the young of migrant fishes, and live less on the carrion of the sea. Still they are more seaward than the birds of higher flight. A bird which fishes over the wide seas almost invariably skims the surface, whereas one which looks out for offal, or fishes at particular places only, takes a higher station in order to look out. Their other structural characters are:—The plumage very close and firm, wings long and pointed, tails short and wedge-shaped, tarsi slender and compressed, front toes long and elastic, and the hind toe a mere claw. Their motion along the surface of the water is exceedingly graceful, especially when there is a heavy swell and they rise and fall to the waves; they manage their wings with so little play upwards and downwards, that they tip the water with the webs of their feet, and thus use the wings for little other purpose than that of buoying them up. From this beautiful gliding over the surface, the people on the British coast call them shearwaters; and where they are numerous they are among the most ornamental birds that appear above the surface of the sea.

They are found ranging through every latitude, except, perhaps, the very coldest ones; and from the odd situations in which stray individuals are often found, it appears that they are not very particular in dashing over a good many degrees of latitude. They have an interest in British ornithology, from the circumstance of one species at least being very common on the north-western coasts, though it rarely makes its appearance on the east. In winter the greater number appear to move considerably to the southward, though a few stragglers still remain on the coasts of the channel, and the South of Ireland. This species is,

The Shearwater (P. Anglorum). *Scotorum* would be a more appropriate name for it, because there are actually more of the birds which breed on a single small island in the Hebrides than there are in the whole of England. This bird is also often called the "Manks petrel," or "Manks shearwater," because it occurs on the shores of the Isle of Man; but that is not one of the localities in which it is most plentiful. They are not resident during the whole year upon any part of the British coast. They arrive on their breeding-grounds about March, and remain till August, during which time they rear a single young one out of a white egg of considerable size. Whilst this operation is going on, one or other of the birds is always very busy in skimming over the surface of the waters, though what their principal food is has not been very clearly ascertained. It is probable that they fish a good

deal, but that the fish which they capture are small. It is also probable that they collect vast numbers of those small animals of various classes which are constantly floating in the sea, and which form the principal food of several of the small-mouthed fishes. Whatever they gather from the waters must, generally speaking, be in small portions, for they merely give a twitch to the surface, and pass on; whereas birds which catch fishes of any considerable size always enter the water in whole or in part, or make some sort of splash. The shearwater, on the other hand, glides along with wonderful rapidity, often combining the three operations of flying, walking, and swimming; and it not only makes forward motion, but wheels and turns and moves laterally with very little apparent effort of wings. Whatever they may feed upon, they must get abundance of it, for, notwithstanding their laborious lives, they are always fat. The young birds are relished by the islanders, who salt them in large numbers as part of their winter provisions. The length of this species is about fifteen inches, and the stretch of the wings about thirty-three; but, as the tail is very short, it is rather a stout bird for its length, though neat and compact in the body. Its colours are plain, but strongly contrasted, being black on the upper part and white on the under; but these are broken into each other where they meet, especially on the sides of the neck. Some of the upper feathers are greyish in their margins, and this is the case during the winter months rather than the summer. The bill is rather longer than the head, and of a dark-brown colour, and the nasal tubes extend to three quarters of an inch in length. As these birds do not collect in large numbers upon any part of the coasts, during the winter, it is probable that they disperse very widely over the ocean, and that they take the advantage of that upturning of the waters during the gales at the autumnal equinox which brings such a supply of food to the surface. We believe that this is the only puffin which comes to any part of Britain to breed; but there are some others which occasionally make their appearance. One of these is

The Ash-coloured Puffin (P. cinereus), which is a native of much warmer climates. It occurs on all the western coasts of Africa, from the Cape to the Straits of Gibraltar, and also in the Mediterranean itself, most numerous, as is said, in the middle latitudes. It differs from the others in being without any distinct nasal tube, or, at all events, in having it very rudimental as compared with the others. It is considerably larger than the former, and it is probable that it is the same bird, or, at most, only a climatal variety of it which occurs in such multitudes in the Australian seas, where the birds nestle in holes of the dry and barren islands and beaches, and, at some seasons at least, appear to return every night to their subterranean dwellings in those places.

There are many other species or varieties of puffin, some of them larger and some smaller. Thus, the blue-billed petrel of the Pacific Ocean is twenty-one inches in length; and the whitish-billed one, found on the shores of Brazil, is as much as twenty-seven. Some of them are, however, much smaller; but, whatever may be their size, or the markings of their colours, their manners are so much alike, and so rarely does even one of them, besides those mentioned, make its appearance on the British shores, that the details of their distinctions have no general

interest. One other species, and only one, has been seen in this country—

The Sooty Puffin (P. fuliginosus). It is understood to have its proper home at the very antipodes; and, therefore, the one which appeared at the mouth of the Tees in 1828 was a stranger indeed.

THALASSIDROMA. Clever as the puffins are in their action upon the waters, they are nothing compared to the storm petrels, or members of the present subgenus. These are small birds, of dark colours, though sometimes there is a little white upon them, and they resemble the swallow tribe, both in colour and in the style and rapidity of their flight. Their dwelling is more exclusively upon the water than that of even the most seaward of the former sub-genus; and they drive about so much, and so incessantly, that it is not easy to say in what particular parts of the ocean they have what may be called their resting-places.

There are several species of the genus, but they all resemble each other very much in appearance, and still more in habits. In calm weather they remain comparatively quiet, each seeking its own food; but in severe storms they endeavour to find shelter, and it is on these occasions that they crowd so much about ships. As they accompany the storm, and sometimes outstrip it in their flight from it, so as to arrive at the ships before it, the sailors look upon it with no small degree of apprehension. They are known at sea as Mother Carey's chickens, among many other names not of the most flattering cast; and this Mother Carey is understood to have been a hag who caused an immense number of shipwrecks in the days of the belief in witchcraft, not only by her supposed influence with the "Prince of the Power of the Air," but by lighting false watchfires on the heights, as used often to be done upon those coasts where the infamous system existed.

The common Storm Petrel (T. pelagica) is the one most frequently met with. It is about five inches and a half in length, but rather more than fifteen in the stretch of the wings; the bill is about half an inch long, and rather slender; the nail on the upper mandible is nearly straight, and the nasal tube is very short: the upper plumage is smooth glossy black, with bluish reflections, and the under plumage is very deep blackish-brown; there are, however, some white feathers on the rump, the tips of the greater wing-coverts, and some of the primary wings. The nests are understood to be made in holes of tall cliffs, but, as the birds fly in and out with great rapidity, the nests are not often discovered. The eggs are two in number, which is double that of the petrels and puffins. Notwithstanding this double produce, as compared with the others, it does not appear that the storm petrels are nearly so numerous; and there is no doubt that it is their exposure to the severity of the weather which thins their numbers. The violent storms not only blow them about like chaff on the surface of the ocean, but they are often driven from inland, where they are left in a state of the greatest exhaustion.

Wilson has given by far the best description of the very characteristic manners of these birds, and as he has given it from his personal observation, to alter it would be any thing but to improve it. When sailing from New Orleans to New York, "on entering," says Wilson, "the gulf stream, and passing along the coasts of Florida and the Carolinas, these birds made their appearance in great numbers, and in all

weathers, contributing much, by their sprightly evolutions of wing, to enliven the scene, and affording me every day several hours of amusement. It is indeed an interesting sight to observe these little birds in a gale, coursing over the waves, down the declivities, up the ascents of the foaming surf that threatens to burst over their heads, sweeping along the hollow troughs of the sea, as in a sheltered valley, and again mounting with the rising billow, and just above its surface, occasionally dropping its feet, which striking the water, throws it up again with additional force, sometimes leaping with both legs parallel on the surface of the roughest waves for several yards at a time. Meanwhile it continues coursing from side to side of the ship's wake, making excursions far and wide, to the right and to the left, now a great way ahead, and now shooting astern for several hundred yards, returning again to the ship as if she were all the while stationary, though perhaps running at the rate of ten knots an hour. But the most singular peculiarity of this bird is its faculty of standing and even running on the surface of the water, which it performs with apparent facility. When any greasy matter is thrown overboard, these birds instantly collect around it, and, facing to windward, with their long wings expanded, and their webbed feet patting the water, the lightness of their bodies and the action of the wind on their wings enable them to do this with ease. In calm weather, they perform the same manœuvre, by keeping their wings just so much in action as to prevent their feet from sinking below the surface." "As these birds," he continues, "often come up immediately under the stern, one can examine their form and plumage with nearly as much accuracy as if they were in the hand. They fly with the wings forming an almost straight horizontal line with the body, the legs extended behind, and the feet partly seen stretching beyond the tail. Their common note of *weeet, weeet*, is scarcely louder than that of a young chick of a week old, and much resembling it. During the whole of a dark, wet, and boisterous night, which I spent on deck, they flew about the after-rigging, making a singular hoarse chattering which, in sound, resembled the syllables *protel-tu-cuk-cuk-tu-tu*, laying the accent strongly on the second syllable *tret*. Now and then I conjectured that they alighted on the rigging, making then a lower curring noise."

We regret that we have no more room for quotation, and we do this the more that the hints contained in Wilson's observations tend to throw more light upon the real characters and economy of these birds than all else that has been written on the subject. He found them in the gulf stream, which shows that they seek the water where it is moving along, and bearing with it those substances upon which they feed. He found the remains of a large fish in the stomach of one, and another filled with tallow which he himself had thrown overboard; in the gizzards of some he found fragments of barnacle shells, and in all he found little globular substances, about the size of mustard-seed, which he conjectured to be the *spora*, or germs of the gulf weed, of which such a mass remains floating in the great central eddy of the Atlantic, and continues sending fragments northward down the stream. He conjectures also that the partiality of these birds for the wakes of ships arises in great part from the turning up of those substances by the motion of the water, and also from the detaching of barnacles from the ships' bottoms by the same

operation, though the refuse which is cast overboard forms also a part of their attraction. These birds display none of that pugnacity of disposition which is so conspicuous among the fulmars of the north, but appear to live in the greatest harmony with each other.

The species which Wilson describes upon this occasion were a little larger in size, and browner in the colour, than those which are met nearer the shores of the eastern continent. Their general structure and also the forms of the tails are the same, however, and therefore, though they have been considered by some as a different species, the grounds of distinction are but slight.

There is, however, another species found in the Atlantic, and also occasionally on the British shores, though but rarely. They are rather larger than the even-tailed ones seen in the east parts of the Atlantic, and they have the tail very spreading and forked, but not very deeply. They are also different in their colours, the upper plumage being brownish; some of the scapular feathers and more of the wing coverts being whiter than in the species which have not the tail forked. Except in the termination of the tail, and that was slightly forked in some which Wilson examined, this bird agrees very exactly with Wilson's birds in size and in shape; and, as he observed some of them with much more white upon the body than others, it is very possible that they are identically the same; that the larger species or variety is chiefly found on the richer pasture of the gulf stream; and that the few stragglers which have appeared on the west coast of Britain may have followed in the wakes of ships from near the American shores. There is another circumstance which increases the probability of this: the greater number of those stragglers have been seen in the winter, and therefore they may be presumed to have followed the ships late in the season, when their breeding operations were over, and they were more dispersed upon the waters.

Of the species or the conduct of those birds upon the Pacific, we have but little information; and that ocean is so much wider than the Atlantic, and so rarely crossed in comparison, that information respecting its birds, and its natural history generally, is not so easily obtained.

PHACOTHERUS—Warty Hog. A genus of the hog family, which has been separated from the others in consequence of certain peculiarities of its structure; but we shall notice those differences, and also the other distinctions of genus or sub-genus which are to be met with in the family under *Sus*, the name of the typical genus.

PHALACRUS (Paykull). A genus of minute beetles. See *ANISOTOMIDÆ*.

PHALÆNA. Linnæus divided the lepidopterous insects into three genera only, *Papilio*, *Sphinx*, and *Phalæna*, or butterflies, hawk-moths, and moths properly so called, the last named genus being characterised merely as follows: "Antennæ setaceous, gradually attenuated from the base to the tips, wings at rest generally deflexed, flight nocturnal." These characters, it is true, have the merit of uniting together a great mass of species, although it is very difficult to draw the line between some of the less typical sphinges and some of the moths. Still, however, the step was so evidently natural, that it has been retained by most subsequent authors. It was however necessary even for Linnæus himself, from the number

of species belonging to the genus, to establish sections as follows:

- I. *Attacus*, with the wings horizontally extended.
- II. 1. *Bombyx*, tongueless, with the wings reversed.
2. *Bombyx*, tongueless, wings depressed, back not crested.
3. *Bombyx*, tongueless, wings depressed, back crested.
4. *Bombyx*, with a spiral tongue, back not crested, wings deflexed.
5. *Bombyx spirilingues*, back crested, wings deflexed.
- III. 1. *Noctua*, tongueless.
2. *Noctua*, spiral-tongued, back not crested.
- IV. 1. *Geometra*, antennæ pectinated, posterior wings rather angulose.
2. *Geometra*, antennæ pectinated, wings rounded.
3. *Geometra*, thread-horned, wings angulose.
4. *Geometra*, thread-horned, wings rounded.
- V. *Tortrix*.
- VI. *Pyrahis*.
- VII. *Tinea*.
- VIII. *Alucita*.

These eight primary divisions have constituted, in the works of most modern authors, the chief primary divisions of the nocturnal lepidoptera. By some authors, however, the name *Phalæna* has been employed in a manner which must surely be contrary to every true principle of scientific nomenclature, namely, as a family name, *Phalænidæ*, for the thread-horned *Geometræ* of Linnæus. We have, however, already in the article *Geometridæ* noticed the additional incorrectness of this step, and shall therefore terminate this article by regarding the term *Phalæna* as synonymous with that of *Nocturna* or *moth*, and referring the reader to the articles under these two heads, as well as to that upon the *Geometridæ*.

PHALANGIIDÆ. A family of arachnidous insects, belonging to the division *Trachearia*, and order *Adelarthrosomata* (see vol. i. p. 186), and distinguished by having the antennal claws very distinct and terminated by a didactyle claw. They have two filiform palpi of five joints, the last of which is terminated by a small hook, two maxillæ formed by the elongation of the basal joint of the palpi, two eyes, and occasionally four other maxillæ composed of the dilated basal joint of the fore legs. The body is short and of an oval or rounded form, the abdominal portion exhibiting the appearance of segments. The legs, eight in number, are always very long and divided as in insects.

These curious creatures are known under the common name of harvest-men or harvest-spiders. They live on the ground amongst grass, under stones, &c., and are exceedingly active, the great length and slenderness of their legs enabling them to proceed with very great rapidity. These insects are evidently rapacious, and feed upon other insects. Their relations are very interesting, appearing to be intermediate between the spiders and mites. Some of the exotic insects belonging to this family are amongst the most extraordinary of annulose beings; the species of *Gonyleptes*, in their threatening form and the singular spines with which the legs, &c., are armed, well merit the specific names, *horridus*, &c., which have been given to them, whilst others, figured by Dr. Pertz in the "*Delectus Animalium Articulatorum Brasiliæ*,"

(wherein a complete specific synopsis of the family is published), are even still more extraordinary. The *Dolichoscelis Haworthii* of Hope, described and figured in the last part of the Linnæan Transactions, covers an area of at least six inches in diameter, whilst its body is scarcely a fiftieth part of this extent. The other principal genera are, *Siro*, *Macrocheles*, *Trogulus*, *Phalangium*, and *Obisium*. There are numerous British species belonging to the two last named genera. The *P. cornutum*, Linnæus, being the male, and the *P. opilio* the female of the typical species of *Phalangium*.

PHALAROPE (*Phalaropus*). A genus of aquatic birds, having, as the name implies, the toes furnished with lobes. They are placed by Cuvier in the longirostral family of *Echassiers*; but it is not very easy to assign them a place in the system which will exactly suit all their habits, because, though their feet are only lobed and not entirely webbed, they are very expert swimmers, at the same time that they are discursive birds, and range to great distances. They are not birds of large size, but they are expert walkers, as well as good swimmers and fliers. Their generic characters are: the bill long, slender, weak, straight, and depressed at the base; the mandibles furrowed for the whole length, and the tip of the upper mandible blunt and curling over the under, which is pointed; this structure of bill is not adapted for very severe labour, and therefore we must suppose that that the birds live upon small substances, though they obtain them sometimes from the land and sometimes from the water; the nostrils are in the sides of the bill near its base, they stand out, and are surrounded by a membrane; the feet are of moderate length, with the tarsi rather slender and compressed laterally; there are three toes to the front, all webbed as far as the first joint, and then furnished with lobes for the remaining length, which are capable of striking the water with very considerable force, and yet of being much more easily recovered than feet entirely webbed. The hind toe is short, turned inwards, and without any membrane; the wings are of moderate length, but rather pointed, and they are clever birds and handsomely formed, but wild, and devoted to free nature. Though there are two of them that visit Britain in the winter, the one not unfrequently, and the other very rarely, yet in summer they seek the extreme north; and if we except the fulmars, there are perhaps no birds which approach nearer to the poles. These species are the red-necked phalarope and the grey phalarope.

The Red-necked Phalarope (*P. hyperboreus*). This is a very handsome and clever bird, almost equally expert at each of the three motions of running, swimming, and flying. It is a discursive bird, migrating northward in the summer, and southward in the winter, in doing which it takes a very considerable range. If we were to judge from the feet only, we should be disposed to say that the coot is the bird which it most nearly resembles; though the toes are much shorter than those of the coot, and the lobes upon them are smaller, and not so much divided. When, however, we examine the bills, and the general structure, we find a remarkable difference. The bill of the coot is decidedly an aquatic bill; and the form of the body, and the articulation of the legs, are so decidedly of a swimming character, that the bird is a bad walker. True to its structure, the coot is found only upon the waters, generally the fresh waters, and

it does not range much. This phalarope, on the other hand, though its form is that of a shore bird, and its march is swift and graceful, while its habit corresponds, as it finds its food, at least in the winter, more upon land than in the water. Notwithstanding of this, the phalarope is by far the better swimmer of the two, and, as we have said, the places of its swimming and wintering are generally widely apart from each other. It is true that the legs are not articulated to the body, or the joints of the tarsi formed in that manner which is the best adapted for a running bird, because such a structure would be incompatible with expertness as a swimmer. The phalarope has, however, less of the awkwardness of the swimmer in its walk than any bird which can be named. Its body, though light, is firm, well shouldered, and exactly of that shape which indicates a good flier.

The following are the colours of the summer or breeding plumage, in which, however, the bird very rarely appears in this country:—The back is black, with reddish brown margins to the feathers; the top of the head, the hind-head, cheeks, and sides of the breast, are ash; there is a white bar across the wing, and the upper tail-coverts are mottled with the same colour; the front and sides of the neck are reddish brown; and all the rest of the under part, and also the skin, white, but with dusky brown spots on the flanks. The female has the general plumage less clear in the tints, and the brown on the neck much paler, and spotted with ash-colour. In the winter, the time when the birds are seen in this country, the black parts have become brown, the brown part pale buff, and the brown spots on the flanks are nearly obliterated. The young birds have the upper part mottled with white and reddish, and the under parts with pale ashen grey. When birds in their summer plumage, and also young birds, first began to be obtained from the northern countries where they breed, there was a good deal of confusion about the species; but the facts are now well ascertained, and the changes of plumage tend greatly to show that the place which Cuvier has assigned to the phalaropes, in his arrangement of birds, is the right one.

The Grey Phalarope (*P. lobatus*). There is a double blunder in the naming of this bird and the last one; for this is the more northerly bird, and ought, on that account, to be called *hyperboreus*, if any of them is to get that name; and the English epithet grey, applied to this one, is the name of its winter colour; whereas, if it is to be named from the colour at all, it ought to be named from the summer, or breeding plumage, because that is the livery of a bird when in its highest perfection.

This phalarope is very rare in England, even in the winter; and it is scarcely more common on the shores of the northern and western isles of Scotland. Indeed, any specimen which does find its way here must be looked upon as a stray bird, which has been beaten from the line of its regular migrations by the violence of the winds. Birds which come in this way do not come at a regular season, like the habitual migrants, but are more likely to arrive in the autumn than in the depth of winter; because, when winter fairly sets in, their migration in their own locality is over—they are comparatively at rest in their winter-quarters, and not exposed to the winds. Such birds are also much more likely to come to the southerly parts of the country than to the northern. Accordingly, specimens have occurred in the southern

counties of England; and one mature male, which was found in Wiltshire as early as the month of August, retained so much of the summer plumage, as to show that the rich-coloured birds found far to the north in summer are identically the same as the grey ones which straggle southward in the winter.

At all times of the year this phalarope is a handsome bird, and in summer its plumage is very beautiful; but the colours are so mottled and broken, that it is scarcely possible to give a detailed account of them. The whole of the under part is then rich reddish brown, passing into a mixture of black, brown, and several other tints, which it is not easy to name, on the back, the wings, and their coverts. There is, however, a white bar across the greater coverts, the same as in the other phalarope, which undergoes no annual change. In winter the colour changes greatly, and in all probability the change is greater in proportion as the place in which the bird winters is colder. As it occasionally appears with us, the brown on the under part has faded to white, marked with some greyish ash on the sides of the lower neck. The colours on the back and wings fade almost to one entire tint of grey, notwithstanding their variety in summer. The most singular change in the plumage, however, takes place in the head. In summer the chin, the cheeks near to the eye, the top of the head, and the hindhead, are deep black; and a small space round the eye, on the cheek below the eye, and backwards to the nape, is white, mottled with a few feathers of brownish-grey, and passing gradually into the dark colour of the neck. In winter, again, those colours of the head exactly change places, by all that is black in summer turning white, and all that is white turning black. There is a seasonal change even in the bill and feet. In summer the bill is yellow, and the feet are blackish brown; but in winter the bill becomes dusky almost to blackness, and the feet lead-colour. In consequence of these changes, both of the feathers and of the naked parts, it would not be easy for any one to believe that the bird, in its two plumages, was still the same species, were it not that it has been seen in all its changes.

The young birds, in their first plumage, have the back and scapulars grey; the greater coverts dusky, margined with buff; the white bar on the wing more conspicuous, and a slight tinge of brown on the throat. Their bills and feet are also much paler in the tint than those of the mature birds in summer. The young might thus readily pass for a third species by those who attend only to colours; and, as they generally move southward earlier than the old birds, they are not only first seen, but most plentiful in the southern parts of the range. It should seem that this bird is chiefly an American, though it does not appear to come abundantly into the south, or even the central parts, of the United States. Wilson saw it, and left a few notes respecting it, but no finished description; and the American ornithologists who have followed him have not exactly come up to his standard in their attempts to furnish one. Indeed, it is only in the extreme north, among that dismal melange of rocks, ice, and water, with which the explorers of those dreary regions had to contend, that this phalarope seems quite at home in the summer. The situation of its nest, and its economy and food in the breeding season, are quite unknown.

PHALARIS (Linnaeus). This genus is the **CAT. HIST.—VOL. III.**

nary-grass of authors, and is one of the cultivated *Gramineæ*. The grain is chiefly used for feeding poultry and singing-birds.

PHARNACEUM (Willdenow). A genus of annuals and undershrubs, having pentandrous flowers, and belonging to *Caryophylleæ*. They are all easily cultivated.

PHASCOLOMYS—wombat. A genus of marsupial mammalia, of which there is only one known species, and this species is so different from all the other mammalia, whether marsupial or placental, that it may almost be considered as forming a distinct order. It is one of the most quiet and peaceable of animals, as perfectly passive as a living creature can be, and it lives upon vegetables, and does injury to no living thing; but at the same time it does not, in the structure of its teeth, fall into any of the order into which the vegetable-feeding mammalia are divided, nor, in fact, resemble them. Almost the only character too in which it strictly agrees with the other marsupial animals, is simply being marsupial. If we were to liken it to any of the placental animals, the rodentia are the ones which it resembles the most in the teeth, and it is very unlike them in form and in habits. It seems that the teeth are not constant in number, but, generally speaking, there are two incisors in each jaw, placed very remote from the grinders, and sometimes with a tooth in the interval, somewhat resembling a canine tooth, but as often without this. Even the incisive teeth do not appear to be constant in their number, but to vary from two to six, to be thick and strong when few in number, and small and weak when many. The small ones are most frequently accompanied by canines, two in each jaw. These canines are crooked, but have flat oval crowns, and nothing of a carnivorous character about them.

The full-grown wombat is nearly the size of a badger. Its body is thick and heavy; its head large and flat; its eyes and ears small, the former moderately opened, so as to indicate an animal that lives partly above ground and partly below; the legs are short, and the fore legs are supported by clavicles, so that they have a cross motion, by means of which the animal can burrow readily in the ground; there are five toes upon each of the feet; but the inner toes on the hind feet are very small and without claws; the claws on the fore feet are very stout, and fitted for digging; and the three middle toes are supported for some length by a connecting membrane; the feet are plantigrade, or have the entire sole applied to the ground in walking; the covering of the body is rough and thick, and of a greyish-brown colour, paler about the ears and neck than on the rest of the body; the tail is reddish-brown, but it is so exceedingly short, as to be almost entirely hidden by the fur of the surrounding parts, and the ears are nearly concealed in the same manner.

The whole of the senses appear to be duller in this animal than in almost any other. It is perfectly passive even to danger; for any one who meets with a wombat may lift it and carry it off, not only without its offering any resistance, but absolutely without its making any complaint. In consequence of the extreme mildness of its disposition, it can readily be made to reside in houses, though it appears to be susceptible of hardly any education. It spends the greater part of the day in sleeping, during which it rolls itself up in the form of a ball. In the wild state it lives entirely upon vegetables; but when kept in

E E

confinement it eats a greater variety of food, and it has no objection to milk. It readily eats all sorts of fruits, roots, and culinary vegetables, and also bread; so that it is just as passive in the taste of its food as in any thing else. It is understood that the seal-fishers about Bass's Straits keep it in their huts, where it is not only as tame as a dog, but a great deal tamer, inasmuch as it is perfectly indifferent to the appearance of strangers. It is not of course to answer any of the purposes of a dog that so dull and passive an animal is kept, but rather to answer those of a pig. The flesh of the wombat is considerable in quantity, and said to be more juicy, more tender, and every way better in quality than that of any other marsupial animal, and the animal itself is certainly more easily taken than any known species of game. For these reasons it has sometimes been proposed that Australia should send the wombat to Europe to become a domestic animal, as some slight return for the European animals which constitute a very important portion of the wealth of the colonists. Two live ones were once in the French museum, but they did not live long, and it is exceedingly doubtful whether so very simple an animal could be kept in a European farm-yard, as the poultry would be very apt to peck at it, and the pigs to trample it to death.

The geographical range of this animal appears to be very limited, being confined to some part of the shores of Bass's Straits, and to the islands situated there. It appears, also, that it is now very rare compared with what it was when those Straits were first discovered; and it seems to be in rapid progress towards extinction, so that, as we have said, an entire genus, and indeed an order, will be blotted out from the living inhabitants of the world.

PHASEOLUS (Linnaeus). A large and useful genus of climbing herbs, natives of many different parts of the warmer parts of the world. The flowers are diadelphous, and many of them very beautiful, the genus belonging to *Leguminosæ*.

The kidney-beans are in every garden, and so well known, that they need no description. There are many species, and of both dwarfs and runners many varieties. The young pods of the dwarfs are one of our most delicate table vegetables; and the scarlet or rough runner, *P. multiflorus*, is one of the most useful cottage garden products.

PHASMIDÆ. An extraordinary family of orthopterous insects, belonging to the section *Cursoria*, and distinguished by the more or less elongated form of the body, exposed head, tarsi five-jointed, posterior wings longitudinally folded, and fore legs simply formed for walking, and not raptorial as in the *Mantidæ*, with which family they were long united. We have taken occasion in various instances of calling attention to some of those curious resemblances which exist between animals or tribes of animals of very different structure; but the creatures now under consideration exhibit perhaps the most striking similarity which could be desired between animals and vegetables. The author of this article has repeatedly been asked, when showing his collections of these insects to persons not versed in such matters, how he could wish so far to deceive them by fastening together bits of stick and old withered leaves, and patching them into something of the shape of insects! for the fact is, that so completely do some of these creatures resemble pieces of vegetables, that their ordinary

names are walking-stick insects, leaf insects, animated leaves, &c.; and surely to see some of them arranged upon a twig as Donovan has arranged them in one of his plates of "Indian Entomology," the deception is complete. But it is not alone in form that this similarity exists, but also in their colours, so that, to adopt an interesting theory propounded by the authors of the "Introduction to Entomology," it would seem as though the Creator had impressed these forms and colours upon these creatures, in order to guard them from the attacks of their enemies, who are thus deceived, mistaking them for portions of the plants upon which they subsist. We are aware that objections may be urged against this theory, and that these kinds of resemblances may be termed merely freaks of nature; but as we know that instances may be produced in which the precisely opposite effect is produced, namely, where predaceous creatures lying in wait for their prey are also hidden as it were from the sight of their victims by the like similarities of appearance, we cannot but think that concealment is as much the object in one case as in the other.

These insects are inhabitants of tropical climates, a very few species of comparatively small size being found in the south of Europe. They delight in remaining stationary upon the branches or twigs of plants. The females are provided with a strong apparatus, enabling them to bury their eggs under the bark of trees. According to the Rev. Lansdown Guilding, who has published an interesting Memoir upon *Phasma cornutum* in the Linnaean Transactions, the insect remains tranquil all day, but at night it devours a great quantity of leaves; its motion in walking is unsteady; and when it loses one of its legs in the larva state, the organ is reproduced, of a smaller size, at the following moulting. The student must consult the Synopsis of *Phasmidæ*, of Mr. G. R. Gray, for fuller details and a notice of the various species, distributed into many sub-genera. The family is divisible, as the names noticed above imply, into two groups or sub-families, *Phasmides*, with the body slender and stick-like, and the legs long; and *Phyllides*, with the body broad, very thin, and more or less leaf-like, and the legs short and dilated. These two sub-families are divided into various generic and sub-generic groups. In the *Phasmides*, some have the antennæ very short (*Bacillus*, Latreille), which, as well as *Bacteria*, Latreille, consists of apterous species. The restricted genus *Phasma* comprises those species which are winged, and possess ocelli. Some of the species of this family are amongst some

Bacteria fragilis.

of the most gigantic of the insect tribes. That which we have above selected for our illustration of the sub-family *Phasmides* is the *Bacteria fragilis* from New Holland, described and figured in Mr. Gray's Synopsis

of the Australian species of this family, from the collection of the Rev. F. W. Hope. The figure is about half the natural length.

PHEBALIUM (Ventenat). A genus of evergreen shrubs from New Holland, belonging to the natural order *Rutaceæ*. In greenhouse collections they thrive well with the ordinary management.

PHILADELPHÆE. A small natural order containing only two genera, viz. *Philadelphus*, and *Decumaria*. Of the former there are fifteen, and of the latter three species, already described. The *Philadelphus* are very ornamental plants, possessed of neither deleterious nor useful properties; but some are so strongly scented as to cause headache when introduced into nosegays. The calyx is turbinate, with the limb in four divisions. Petals four or five, inserted into the calyx. Stamens attached to the throat of the calyx, and shorter than the petals. Style four or five parts, stigma oblong, capsule four or five-celled and many-seeded.

The *Decumarias* are climbing shrubs from North America, with icosandrous flowers, having a many-toothed bell-shaped calyx. Petals from seven to ten, stamens numerous, anthers double, style cylindrical, stigma peltate, with many rays, capsule valveless, and many-celled. They are hardy plants, and increased by layers or suckers.

PHILANTHUS (Fabricius). A genus of hymenopterous insects belonging to the fossorial *Aculeata*, and family *Crabronidæ*, but confounded by that author with the genus *Cerceris*, Latreille, from which it differs in having the abdominal segments not narrowed at the base, without any peduncle, and with the second submarginal cell not petiolated as in *Cerceris*; with this genus, however, it agrees in the predatory nature of its habits, and which render the *Philanthi* some of the most obnoxious of insects in places where they abound. Fortunately only one of the species has been found in this country, *P. androgeneus*, Rossi, and that occurs but very rarely. The typical species, *P. apivorus*, has formed the subject of a very interesting memoir by Latreille, of which the following is a concise abstract. The females of this insect make their nests in sandy places, where they form deep and cylindrical burrows, in which they deposit a considerable number of honey bees, (*Apis mellifica*), which they slightly wound with their sting at the moment when they bury them, their victims still retaining a little life, and capable of a little motion, which is to be perceived even at the end of many days. When the nest is sufficiently stored with these poor insects, the females deposit an egg in the midst, and close up the cell. They then commence another nest for the reception of another egg, and so on until their supply of eggs is completely exhausted. Latreille, in order to ascertain the amount of destruction which a hive in the neighbourhood of the nests of these insects might undergo, opened, in the first place, the body of the female *Philanthus*, in order to count its eggs, and thus he ascertained that the ovary appeared only to contain five or six eggs, of an elongated cylindrical form, and white colour. Each female, therefore, destroys at least six bees, and probably a greater number, as Latreille could not assert that each larva consumed only one bee, many of which were rejected and others abandoned. Latreille moreover counted on a space of ground, 120 feet long, about fifty or sixty female *Philanthi* occupied in the con-

struction of their nests. This space of ground, therefore, at the lowest calculation, must be the tomb of between three and four hundred bees.

The larva is produced from the egg in a very short time, and in a few days consumes the food laid up for it in store. It then forms a cocoon, which appears rather to be a viscid secretion, than to be spun with silk, and which when dry becomes a flexible membrane. Within this cocoon the larva remains unchanged for many months, and does not become a pupa until the end of the winter, and hence there is only a single generation in the course of the year. The food of the different species varies in its nature, some preferring *Andrenæ*. In the perfect state, they very much resemble wasps, and feed upon honey, and the nectar of flowers; whence evidently is derived the generic name, which signifies lovers of flowers. This genus is not numerous in species; and the colour of the insects is generally black, varied with yellow.

PHILEDON—NECTAR-SUCKER (*Meliphaga*). A genus of anizodactylic birds, which, as their name imports, subsist, in great part, upon the sweet juices which they gather from the nectaries of flowers. This is a peculiar mode of feeding for birds, and these birds are peculiarly organised, so as to adapt them to it. They also inhabit peculiar localities, where the productions of the vegetable kingdom are of a different character from what is met with any where else. The species of this genus are numerous; but notwithstanding their numbers, they are not generally distributed even in corresponding latitudes. There are none in America, in Europe, in Africa, or in continental Asia; and we believe there are few in those Oriental Isles which may be considered as partaking of the Asiatic character, or intermediate between it and the islands which spot the wide Pacific. New Holland, and especially the scattered isles which geographers include under the general name of Oceania, are the only countries where birds of this genus are found; and though there are many of them in European museums, and some of them are very numerous in their native countries, their manners are very little known.

In the isles and regions of perpetual verdure, where some plants are always in flower, and many trees are rarely found without both flowers and fruit, these birds keep constantly flitting about from spray to spray, collecting the means of their subsistence.

They have frequently been confounded with other tribes of birds, such as the bee-eaters, the creepers, and even the thrushes, from all of which they are separated by distinct characters and habits, so far as the latter are known or can be guessed at. It is highly probable that the mistakes of the more early describers, respecting their proper place in the system, have been among the causes why so little attention has been paid to the ascertaining of their proper function in nature. This is indeed greatly the case with all the birds of Oceania; and yet in their numbers, the beauty of their plumage, and the singularity of some of their forms, they are among the most interesting of all birds. It should seem, however, that those who visit these islands are far more anxious to bring home the mere skins of the birds, often mutilated or in bad condition, than to bring any portion of their history, or of the relations which subsist between them and the other productions of nature in the countries which they inhabit. The absence of

this information is a sad breach in the continuity of our knowledge of the growing and living world ; but it is a breach which cannot in the mean time be made up, and therefore we must content ourselves with a statement of the generic character, and of the sizes and colours of some of the species.

The generic characters are as follow : the bill not longer than the head, of moderate thickness, a little convex, sharp, and curved a little toward the point, which is furnished with a notch in many of the species. The bill is depressed at the base, where the culmen advances a little on the forehead, and the cutting edges are margined. The nostrils are in the sides of the bill, at variable distances from the base, and covered in part by an arched membrane, which is naked of feathers. The nasal grooves in the bill are large, and produced toward the point. The variations in the positions of the nostrils, and especially the presence or the absence of a notch in the bill, would lead us to conclude that there are sufficient differences of habit among these birds, for warranting the separating of them into several genera ; because the notched bill is decidedly insectivorous in its character. The tongue is peculiar ; it is lengthened, a little extensible, and furnished with a bunch of cartilaginous fibres at the tip, by means of which the bird is understood to collect the sweet juices ; the feet are of mean length, containing four toes, there are three in the front and one in the rear, the hind one is furnished with a very powerful claw ; the wings are of moderate length, and rounded, the fifth quill being the longest. This form of the wings is against the birds' taking long flight ; though it is the best form for enabling them to beat easily at short distances over plants and trees in search of food. The species as enumerated in the books amount to about sixty, varying from five inches in length to about ten or eleven ; and not so remarkable for the brightness of their colours as many other races of birds of the same country.

Spotted Philedon (M. maculata). This species belongs to the remote isles of the Pacific, and is about five inches and a half in length ; the upper parts yellowish green ; the chin and space round the eyes deep grey, marked on the top by a white band passing from the gape over the eyes ; the ear coverts golden yellow ; and the under parts greenish yellow spotted with brownish ash ; the bill is red at the base and black at the point, and the feet an ash colour. The female is brown above, with the top of the head ash ; and nearly white on the under part, but mottled with little blue spots on the breast.

Black and white Philedon (M. melanoleucos), is a New Holland species, about six inches in length. It is grey on the upper part, brown on the forehead, with a white spot over each eye ; the quills and tail feathers are black, with some of their webs yellow and others grey, and the tips of the outer tail feathers white ; the middle of the breast and the belly are black ; the flanks grey, the feet brown, and the bill black.

Yellow-winged Philedon (M. pyroptera). This is another New Holland species, about six or seven inches long. The upper part shining grey, with a yellow spot on the ear covert, and a little brush of black feathers above it ; the rump is yellowish ash ; the quills and tail feathers are yellow with the exception of the two middle ones of the latter, which are black ; the under parts are whitish, streaked with delicate lines of grey on the breast ; the bill and feet

are black. The female has the quills rusty red ; and the under part yellowish, mottled with russet on the belly.

Such are one or two examples of the genus *Philedon*, and though we were to enumerate the whole sixty species, we should not be able to add much, or indeed any additional information, numerous as the birds are.

PHILLYREA (Linnæus). A genus of evergreen hardy shrubs, having diandrous flowers, and belonging to the *Oleina*. They are some of our most common shrubby plants, and are propagated by layers.

PHLEUM (Linnæus). A genus of useful grasses mostly natives of Europe. The *P. pratense*, major and minor, are the cats-tail grasses of the British farmer, and are common in every meadow.

PHLOMIS (Linnæus). A genus of shrubs and herbaceous perennials, mostly European, and belonging to *Labiata*. The *P. fruticosa* is called the Jerusalem sage, an ornamental plant common in our shrubberies. All the species are more or less showy, and are all easily propagated.

PHOCA, the genus seal, or perhaps more correctly, *Phocidæ*, the seal family, an account of which in their relations, habits, species, and commercial uses, will be given in the article **SEAL**.

PHRENOTRIX. A somewhat peculiar genus of birds, intermediate in its character between the crow tribe and the birds of paradise, but distinct from both. There is only one known species, a native of the Sunda Islands. The characters are : the bill of mean length, very stout, high in the culmen, wide at the base, having the mandibles a little curved, and convex and smooth on the side. The head is large, and covered with silky feathers very thickly set. The nostrils are small, at the base of the bill, and in the form of transverse slits. The wings are broad and rounded, the third and fourth feathers being the longest. The tail is longer than the body, consists of ten very strong feathers, and is much wedge-shaped at the extremity, approaching in some respects to the shape of the tail of a magpie. The feet are very stout, covered with shielding scales on the interior, with three toes to the front and one to the rear. They are of moderate length, but all the claws on them are strong and compressed, and that on the middle front toe is rather longer than the others. The whole structure of this bird points out that it is a short flyer, practising a good deal of ascent and descent, and spending a considerable part of its time on the ground.

There is only one known species, which is an exceedingly common bird in the Island of Java. It is not a gaudy bird in its plumage ; but still it is a rich one. Its general colour is a sort of brownish smoke-grey ; but glossed with reflections of every tint of colour between bright green and yellow. The head is deep black ; and the coverts of the wings are shining olive green. Its total length is between fourteen and fifteen inches, of which the tail occupies more than one half. Plentiful as it is in its native country, its manners have not been much studied ; and that such should be the case, is matter of regret. It is unquestionably what is usually termed a connecting link between the crow tribe and the birds of paradise. We know the habits of the crows abundantly well ; but we are very ignorant of those of the birds of paradise. It is highly probable that if the habits of this one were diligently studied, they would lead us to at least some knowledge of the habits

of the others, which are so interesting in their appearance, from the singularity of their plumage. See BIRD OF PARADISE.

PHRYGANEÆ (Linnæus). An extensive genus of insects, constituting, in the system of Latreille, the third and last great section of the neuropterous order *Plicipennes*, but formed by Mr. Kirby into a distinct order, *Trichoptera*. Without entering into the question of the ordinal or other rank of this tribe of insects, it will be sufficient to state the chief characters in which they differ from the other neuropterous insects. The mouth is of an obsolete character, the mandibles being either entirely wanting or minute and membranous, as are also the under jaws and lip; the palpi are, however, present, which of course proves the presence of the organs of which they are appendages; the posterior wings are generally larger than the superior, and folded longitudinally when at rest, at which time the organs of flight are laterally deflexed, the anterior pair being more or less pilose, and the nervures are for the most part longitudinal, and branching with very few transverse connecting nerves; the eyes are prominent and globular, the ocelli two in number; the abdomen soft, and not furnished with terminal setæ; and the legs are long and slender; the coxæ elongate, and the tibiæ generally furnished with one or more pair of spurs; the tarsi are five-jointed. These insects are found in the neighbourhood of water, and are called caddice-flies or water-moths, and their larvæ caddice-worms, in

which latter state they reside in the water in cases of sand, shells, &c. (fig. A) as described in the article CADDICE WORM. Both in their larva and perfect state they are excellent baits for fishing. The pupa is inclosed within the case formed by the larva ; it is of that species termed incomplete, having all the limbs distinct, but folded upon the breast, the head being, moreover, furnished with a pair of curved mandibles, which appear to be applied to no other use than that of making a passage through an open-work grating of silk (fig. B), which the larva had formed at the opening of its case previous to assuming the pupa state. This grating hardens in the water, and becomes indissoluble ; strong threads crossing each other forming a small thickish circular plate of brown silk, which becomes as hard as gum, and fits exactly into the opening. De Geer has described and figured several of these cases thus grated at one end ; and Reaumur has ascertained that the holes left in the grating were for the purpose of breathing, by admitting a current of fresh water, effected evidently by the spiracles of the pupa ; and he actually saw the grate-work in alternate motion, from convex to concave, as the water passed out and in. When,

therefore, the time arrives for the insect to quit its watery abode, and assume the winged state, it is endowed with powers of motion far greater than are possessed by any other incomplete pupa, so that it is enabled not only, in the first place, to cut through the grating of silk, but afterwards to creep out of its case, and ascend into the air, where it throws off its outer skin, and appears as a caddice-fly (fig. C.) The species are found flying, chiefly after sunset, about streams, ponds, &c. They are of a small or moderate size, and generally of obscure pale brownish colours. They greatly resemble each other in general appearance, although sufficient characters are to be found in the nerves of the wings, the form of these organs, colours, &c. Dr. Leach divided this tribe of insects, as an order, into two families, *Leptoceridæ* and *Phryganidæ*; but M. Pictet, in a very valuable work, recently published, upon the *Phryganææ* of Switzerland, has divided them in the following manner, according to the structure and habits of their larvæ, which he confirmed in a subsequent table founded upon the characters of the imago.

I. Larva, with a case opening with a round hole.

1. Segments of the thorax rounded, external respiratory organs isolated. *G. Phryganea*.

2. . . . in tufts.

a, Hind legs long,

G. Mystacida.

b, Hind legs short,

G. Trichostoma.

II. Larva, with a case opening by a cleft,

G. Hydroptila.

III. Larva, without a case.

a, Pupa, with a double envelope,

G. Rhyacophila.

b, Pupa, with a single envelope,

G. Hydropsyche.

In addition to these genera, Messrs. Stephens and Curtis have respectively proposed various others in their more recent works.

The genus *Phryganea*, as restricted, now comprises those species which have the posterior wings larger than the superior, and longitudinally folded, with transverse nerves; the maxillary palpi of moderate length, and slightly hairy. In the genus *Mystacida* the palpi of the males are very long, hairy, and porrected, resembling a pair of legs, and the antennæ very long; they are of small size, and fly in swarms over the surface of water. The genus *Hydroptila* comprises the species of smallest size, which have very much the resemblance of minute moths.

PHRYNUS (Olivier ; **TARENTULA**, Fabricius). An extraordinary genus of arachnidous insects, belonging to the order *Polymerosomata* of Leach (*Pedipalpi*, Latreille), and forming the type of the family *Phrynidae*, in which the abdomen is attached to the thorax by a narrow peduncle, or by a portion of its basal diameter, without the curious comb-like appendages found in the other family of this order (*Scorpionidae*) ; the antennal claws are small and incurved ; the palpi very large and spinose, resembling legs, forming a kind of hook ; they have eight eyes ; the body is flattened, and the insects resemble large spiders ; the anterior legs are very long, and terminated by a slender and multi-articulate tarsus. They are of considerable size, and inhabit the tropical parts of Asia and America. *Thelyphonus*, Latreille, differs in having the body longer, and terminated by a jointed tail. The *Phalangium reniforme*, Linnæus, is the type of the former genus ; the *Phalangium caudatum* of the latter.

PHYLLIUM—Walking-leaf Insects—(Latreille). A genus of orthopterous insects, belonging to the family PHASMIDÆ (which see), and forming the type of the second sub-family *Phyllides*, which consists of the genera *Phyllium* and *Prisopus*, divided by Gray into several others. In *Phyllium* the females are not furnished with posterior wings, and their antennæ are very minute; whilst in *Prisopus* the females have both wings and wing-covers, and their antennæ are of moderate length. The *Prisopus horridus*, figured in our plate of orthopterous insects, is from Mexico, and has not before been represented.

PHYLLOSOMA (Leach). A genus of crustacea, belonging to the order *Stomapoda*, and forming the type of the second family *Bipeltata*, Latreille, (*Phyllosomidæ*). These curious animals are called glass-crabs, from the slender and transparent form of their bodies, which is very flat and membranous, divided into two shield-like plates, the anterior very large and oval, forming the head, and the second, or thorax, transverse and angulated. The legs are very long and slender, and each is furnished with a small ciliated branch. These delicate creatures are found in the tropical parts of the Atlantic and Indian Ocean, and one has been discovered in the Mediterranean. When alive they are entirely colourless, except the eyes, which are of a rich blue. There are several species described by Leach and Guerin.

PICUCULI (*Dendrocopus*). A genus of anizodactylie birds, nearly agreeing in the structure of the feet with the creepers of Europe, but in some other respects partaking of the characters of the woodpeckers. They have been variously classed by writers on ornithology, being distributed through various genera, and not agreeing very well with either of them. They were first brought out of this confusion and formed into a separate genus by Temminck; and, though they vary a good deal in size in the different species, the genus is far from being an ill-defined one.

The generic characters are: the bill depressed and triangular at the base, compressed or slender at the point, not furnished with a tooth, straight in some species and curved in others, and with scarcely any nasal grooves; the nostrils are placed laterally at the base of the bill, they are oval and open; the tongue is cartilaginous, but short, and has none of the peculiar characters of the tongues of woodpeckers; the feet are of mean size, and the tarsus is never longer than the middle toe, and sometimes a little shorter; the external and middle toes are of equal length, and united as far as the second joint; the inner front toe is very short; and all the toes are furnished with very sharp and crooked claws, furrowed on their under sides so as to be able to keep their hold upon very slight inequalities of the bark of a tree; the wings are of moderate length and rounded, the fourth and fifth quills being the longest; but the quills fall upon and support each other in a way which gives great firmness to the point of the wing; the tail is wedge-shaped, or rather oval, at its extremity; the shafts of the feathers in it are remarkably strong and stiff, and have firm points beyond the webs, as in the woodpeckers.

From the structure of the tail, we can easily infer that these birds can make use of that organ as a support, while they hold on with the claws upon the upright stem of a tree. In consequence of the structure of the feet, they cannot hold on so firmly or so long as the woodpeckers; but the same structure which ren-

ders them inferior in this respect renders them superior in another, namely, in running in all directions along the bark as the creepers do. It is probable that they are not quite so dexterous in this way as the creepers, the rapidity and variety of whose motions are truly wonderful; but the support of the tail enables them to perform severer labour at one place. Their bills, though rather firm and strong, are not equal to the task of making a hole in wood, or even in hard bark, and the absence of a notch shows that the birds do not feed upon large insects. We know but little of their manners, because they remain in the forests, and move so nimbly, that it is difficult to get a sight of them. It is the same with the creeper. It is far from being a rare bird in the extensive woods of Britain; and yet one may pass fifty times through a wood without seeing one. It is understood that the picuculi pick out, from the little crevices of the bark, the insects, larvæ, and eggs, which have been deposited there; and, from the numbers and activity of the birds, the services which they render in this way must tend greatly to preserve the trees. They are understood to nestle in the holes of trees, though they never excavate holes for themselves; their eggs vary from four to six, and they are very attentive to their nests.

They are distributed through all the wooded parts of South America, and so far as is known they are peculiar to that country. They also appear to be more numerous in Paraguay and Brazil, than in the valleys of the Amazon and Orinoco, or on the rich shores of Guiana, although in all probability the apparent difference arises as much from the difficulty of seeing them in the very close forests of the places last mentioned.

It is to be regretted that we know so little of a genus of birds containing seventeen or eighteen species, all confined to one locality of the world, and all at work in preventing the trees from being attacked by their smallest and most dangerous destroyers. Their presence in South America and in no other place, shows that the trees there want protection in a manner a little different from those any where else. Before, however, any thing like correct information respecting the forests of South America and their living inhabitants can be obtained, the relations must be traced between all the races of birds which are at work upon and among the trees, and the relative value of each carefully estimated. If done, this would be a work of great value; but the labour of doing it would be immense, if not altogether insurmountable. We shall mention only one or two of the species.

Great Picuculi (*D. major*). This species is from Paraguay, and is the largest of the known ones, being more than twelve inches in length. The general plumage is a reddish-yellow brown, streaked with black and white on the fore neck and breast, and there are also some streaks of blackish colour on the rest of the under part. The bill is large, a little bent, and of a blue colour; and the feet are greenish.

Straight-billed Picuculi (*D. angustirostris*). This is also from Paraguay, and about three inches in length. It is russet-brown on the upper part; has a white streak over each eye; and the top of the head, the nape, and sides of the neck, mottled with black and white. Wing-coverts and tips of the quills brown, but the bastard wing white; the throat is also white, and the rest of the under parts whitish, clouded with brown spots. The bill is brown on the upper man-

dible, and whitish on the under; and the feet are lead colour.

Red-winged Picuculi (D. rubicundus). This is also of Paraguay, and the smallest and handsomest in its plumage of the whole genus. Its total length is five inches. The upper parts are brown, lightly glossed with gold; the sides of the head spotted with brown and white; the smaller coverts of the wings and the tail feathers are carmine red; the larger coverts brown with red borders, and the lower parts mottled with brown and white; the bill is black above, and whitish below.

White-throated Picuculi (D. albicollis). This species is of Brazil, and measures six inches in length. The upper parts and the breast are brown, streaked longitudinally with white; top of the head black, spotted with russet; wings russet-brown; bill and feet also brown.

Such are a few of the species; and, in the state of our information respecting the economy of the birds, an enlargement of the details would afford no useful information.

PICUMNUS. A genus of birds, containing three or four birds with zygodactylic feet, which were once confounded with the woodpeckers, though they are perfectly distinct. They are very small birds, most of them being less than four inches in length, and the very largest not much more.

The characters of this genus are: the bill straight, conical, pointed at the tip, higher than broad, and without any distinct crest; and the two mandibles are of equal size and strength, and entire in their margins without any notch; the nostrils are basal and lateral, linear in their form, and concealed by feathers which project forward from the front; the tarsi are short, and the toes three or four, always two to the front, and consequently one or two to the rear; the front ones are united as far as the first articulation, but the hind ones are entirely free; the wings are much rounded; and the shafts of the tail feathers are flexible, so that the tail cannot be used as a means of support upon the bark of trees, as it is in the preceding species and the woodpeckers. It is worthy of remark, that both these birds and the woodpeckers should have such a variety in the genus as that some should have four toes and some only three, though it does not appear that there is any considerable difference of habit connected with the different structure. Very little is known indeed of the habits of these birds; but it is said that they are found on the stems of bushes rather than those of trees, and that they perch crosswise. It is probable that, with this difference in the magnitude of the plants upon which they climb and seek their food, their general manners do not differ greatly from those of the other insectivorous climbers to which they are allied; and it is even said that they dig into the bark in the decayed places of trees, something after the manner of woodpeckers. They are found only in the woody parts of tropical countries, though they are more abundant in America than on the eastern continent. They have not been observed in Africa or continental Asia, though one species at least has been ascertained to inhabit the Sunda Isles. They have no general English name, having generally been regarded by English describers as small woodpeckers.

P. abnormis. The specific name is given to this one, because it has only three toes, in a state so developed, as to be of much use in climbing. The

internal toe behind is nothing but a little callosity, marking the place of the toe, as in the three-toed woodpeckers. This is the smallest known species; and it is a very little bird, being only three inches in length, which is three quarters of an inch shorter than the golden-crested wren, the smallest of British birds. Indeed it is so very small, that it can with difficulty be seen in the thick forests, where it finds its food. The upper parts are beautiful green, clouded with ash colour on the hindhead; the forehead, the space on the eyes and the cheeks, are maroon brown, with a circle of naked red membrane surrounding the eye; the rump and under parts are russet, with reflections of yellow; the coverts are black, and the bill is black on the upper part, and reddish white on the under; the feet are reddish brown. Notwithstanding its diminutive size, it is a gaily attired little creature, but we know scarcely any thing of its habits.

P. minutus. This is rather larger than the Javese species; but we believe it was named before that was discovered. It is a native of the forests of tropical America, and is probably much more extensively distributed than has been hitherto ascertained. Its length is about three inches and a quarter; and like all the American species, it has four toes on each foot. The upper parts are brown, powdered over with a number of brown and white spots; and the cheeks and rump brownish, powdered in nearly the same manner; the forehead, and part of the top of the head, are exceedingly bright red; the quills are brown, and so are the coverts, but the margins of the first are paler than the middle of the feathers, and those of the last are darker; the under parts are yellowish brown, streaked with dark brown; and the feet are lead colour.

P. exilis. This species has been brought from Brazil, but it is highly probable that it occurs in many other parts of America. It is larger than the preceding one, though still a quarter of an inch shorter than our golden-crested wren; the upper parts are brownish ash; the top of the head black, delicately marked with very small white spots; the forehead, the nape, and the cheeks are orange red, passing into whitish on the sides of the neck; the primary quills have the exterior borders brown, the middle coverts are whitish, and the tail feathers black and brown; the under parts are whitish, the bill brown, with black at the base of the lower mandible, and the feet are russet.

P. cirratus. This also is from South America, and it is the largest of the known species, measuring fully four inches in length; the upper parts are brown, with the margins of the quills and wing coverts paler. The top of the head is furnished with long feathers, which are capable of being erected into a large and rather handsome crest. These feathers are intense black, finely spotted with pure white. The forehead is bright red; the cheeks are cream colour, with a white eye-streak, and a brown spot on the ear covert; the tail feathers are blackish, with a white band on each exterior, one mottled with black, and half the two middle feathers is entirely white; the under parts are whitish, clouded with brownish, and streaked with deep brown on the flanks; the bill is whitish in the greater part of its length, but black at the tip, and also at the base of the lower mandible.

The species above enumerated include all that are contained in this singular genus; and the birds are peculiarly interesting, as composing the last and

smallest genus which have the especial protection of the wood of trees committed to them. The woodpeckers, which we find in greatest abundance in temperate, and even in cold latitudes, stand at the head of this grand division of birds, which ought, in a natural system, to form a separate family; for though some genera are zygodactylic, and others anizodactylic, yet this difference of the feet is not sufficient foundation for distinguishing the groups. Besides this, we have seen that the zygodactylic have the feet differently modified, and consequently adapted for different kinds of motion upon the trees; some of the woodpeckers, and also of the genus under consideration, having only three toes, while the typical birds have four. From the difference in size between the outer and inner toe in the feet of the three-toed birds, the outer toe answers nearly the same purpose as the outer and middle toes of the anizodactylic foot. There is also a closer approach than this in the structure; for the two outer toes of the anizodactylic foot are united a considerable way at the bases. Both this foot and the three-toed foot have therefore a point of support less, than is possessed by the four-toed zygodactylic foot; and it is a remarkable fact in nature's mechanics, that whenever an organ is to have motion in an additional number of directions, the structure of the organ is always simplified. The woodpeckers, whose most laborious work, that of punching large holes in the trees, requires that they should remain firm and stationary, in an upright position, for a considerable time, have the feet with four points of support upon each, nearly equally balanced backwards and forwards. The parrots, and other birds which climb by grasping, and rarely if ever change their position by simple motion, have the grasp or clutch of the foot of the very best form for their habit. The birds which have the points of support in the feet reduced to three, whether the outer one in front is one single toe, or two partially united, are on the other hand formed for running in almost every direction upon the stems or branches of trees, without clutching or any other means, except holding on by the claws; and they may be considered as really having the hardest labour of the whole. The woodpecker may be compared to a mason on his scaffold; the parrot to a gardener on a tree gathering apples; but the bird which runs on the bark has nothing corresponding to it in human action.

We have purposely selected such names as should bring those three genera of birds together, in order that the grounds of all their agreements and disagreements might be at once understood by the reader; and we have entered somewhat at length into the particulars, because these birds, taken in conjunction with the trees which their labours so tend to preserve, are among the most interesting productions of nature.

PICUS—woodpecker. An extensive and well-defined genus of *zygodactylic* or yoke-footed birds, distributed over most parts of the globe, and performing a very important function in the economy of nature. Woodpeckers are generally speaking handsome birds, neatly and stoutly made, remarkably firm in the texture of their plumage, and generally speaking handsomely coloured.

The genus are very easily defined, both by their structure and their habits. The bill is long, straight, supported by angular ridges, and remarkably hard and firm in its texture, especially toward the tip, which is

however generally worn smooth by the severe labour which the birds have to undergo; the tongue is slender and very extensible, being capable of being projected beyond the tip of the bill, by the action of the long horns of the *os hyoides*, or proper bone of this tongue. The point of this tongue is doubly furnished for capturing the prey upon which the birds feed: it is beset with cartilaginous barbs, approaching to the consistency of horn, and inclined backwards; and it is furnished with a glutinous secretion, by means of which it can readily take up small substances, and convey them into the mouth of the bird, when the tongue is drawn backwards; the tongue can be withdrawn with great rapidity, by means of two muscles which are coiled round the trachea; and when these act, the horns of the *os hyoides* are drawn till they stand directly upwards, and the tongue is folded back towards the entrance of the gullet. This action of the tongue, by the muscles which move it not being in any way inserted in the bones of the head and neck, is quite a distinct motion from that of the bill, and may be carried on independently of it; the muscles which move the bill and head are still more powerful, so that the point of the bill acts like a chisel or rather like a little pickaxe, by means of which the bird very speedily punches a hole in the wood of a tree. This is the means by which the race obtain by far the greater part of their food, which consists of insects and larvæ, especially the latter; and those larvæ are most abundant in trees after they have passed the maturity of their vigour, and are in an incipient state of decay. The rapidity with which a woodpecker pecks away at its work is almost incredible, and the strokes cannot be counted, nor is it easy to see the motion of the head and neck. The feet are well adapted for holding on, or ascending the vertical trunk of a tree; but they are not so well adapted for descent, so that when the bird takes a more downward direction it must, generally speaking, have recourse to the wing. It can however make its way laterally with great ease; and a woodpecker can get round the bole of a tree much faster than one who is observing it can get round the root.

Woodpeckers have in fact the especial charge of forests which are allowed to perish by natural decay. In such forests they are exceedingly numerous; and in most parts of the world, whether the temperature is hot, temperate, or cold, woodpeckers are there to perform their labours. In America they are exceedingly numerous; though they are most so in North America, inasmuch as many of the trees there are very subject to decay. They occur also in all the wooded parts of Europe, of continental Asia, of some parts at least of Africa, and of the eastern islands more immediately connected with Asia. We are not aware that any true woodpeckers, or at most only one species, have been hitherto found in New Holland, or in the islands of the Pacific; and it should seem that decaying trees in these places, and also in many parts of Africa, are attacked by insects in a different manner from what they are in those countries where woodpeckers are abundant. The attack there is made by the mature insects mining into the heart of the tree, reducing the internal part to dust, and leaving the external crust sound, whereas it is the larvæ which are hatched in the decaying wood, or which mine between the wood and the bark, of which the woodpeckers have charge.

Their labours in those countries where they abound,

are easily observed, and the use of them in the economy of nature is well understood; but we are not so well acquainted with those characters of the vegetation of countries where there are no woodpeckers which enable them to be dispensed with, and still all the purposes of nature in the forest to be kept up.

As the woodpecker may be said to be made for the tree, the tree appears to be made for the woodpecker. In the former respect, the adaptation of the bird extends even to colour; for woodpeckers found in countries whose forests are different, are differently coloured. Then the bird is quite at home in the tree, which is to it the scene of all its operations. It is its dwelling, its pasture, the resting place for its young, and occasionally as is said a sort of rude musical instrument, by means of which the bird calls, and its mate answers to it.

The sound of the woodpecker is not so frequently heard in the winter; but when the spring begins to call the slumbering world to new life, the woodpecker soon partakes in the impulse of the season. Its first, or at all events its loudest labours, of hammering the tree, are not for the purpose of feeding itself, but seem rather to be a kind of pairing call; and it is not a little remarkable that this call should be a repetition of that sound which the bird most frequently makes in the performance of its appointed labour. The male woodpecker is said to be the one which practises, or at all events begins, this curious species of signal-giving. He finds a hollow portion of the tree, and beats it like a drum with varied pitches and cadences. If a female answers, a place for the nest is soon looked for; and if it be necessary to excavate any portion of the tree in order to make the nest big enough, the pair feed and labour by turns until it is accomplished. They seldom mistake their proper tree, or the proper place of the tree, either for nestling or for a supply of food. We must not wonder at this, or give the woodpecker credit for any forethought purpose; because there is no more approximation to reason in any thing that a woodpecker does after it comes out of the shell, than there is in its coming out of that shell a woodpecker and not any other bird. Still woodpeckers, both on their own account, and on account of the fact of their being closely associated with the majesty of forests, are highly interesting creatures, and we regret that we cannot, consistently with our limits, go farther into their general history. As little can we afford to enumerate all the species, which are very many; but must content ourselves with one or two of each great division of the world in which they are found.

The Green Woodpecker (P. viridis). This is by way of eminence the woodpecker of Britain, at least in those parts of the country where the woods consist chiefly of deciduous trees, and the same may be said of great part of continental Europe. As such it has been long known, and has as many names even, in the English language, as a Spanish hidalgo. The length of the green woodpecker is about thirteen inches, and the stretch of its wings about a foot and a half. The bill is two inches long, and of a dusky colour. The tongue is of considerable length. The irides is white, the eyes are surrounded with black, beneath which, in the male bird, there is a crimson spot bordered with black, which, in the female, is entirely black. The feathers on the top of the head are dusky, with cinereous tips. The lesser

coverts of the wings, the scapulars, back, and neck, are green. The quills are dusky, the greater ones being spotted on each web with white, and the lesser faintly spotted with the same colour on the exterior webs, and richly bordered with green. The rump is pale yellow; the coverts of the ears and whole under parts are of a pale yellowish green; the feathers of the tail are strong and pointed, alternately barred with dusky colour and green, tipped with black, except the outer ones. The claws are pretty much hooked; and the naked parts of the legs are ash-coloured. This species generally have four or five eggs in a hatch. They are of a transparent white or greenish hue, marked with little black spots. They are placed among the rotten wood in a hole of a tree, generally some fifteen or twenty feet from the ground. Sometimes a little wool or soft vegetable substance is used as a bed for the eggs, but this is more frequently dispensed with. In the breeding season the pair are very affectionate, and seldom separate. They are uncommonly regular in their habits, go early to rest, and do not leave their nest till sunrise. The practice of early roosting is also observed by the young birds, which may be seen scrambling about the tree in which their nest is situated, some time before they are able to take wing. If it is intended to attempt the taming of these birds, it must be begun very early, and even then the chance of success is very slight. They are very strong, and very impatient of confinement; and they use their bills with great effect upon all wooden substances to which they have access. There is, however, no great inducement to the taming of them, as they have no song to compensate for the trouble.

There are two if not three woodpeckers which occur in Europe besides the green one, and one of them at least occurs in some of the upland and lonely woods of the British islands. None of these is so large as the green, and they are more broken in the colours, hence they are called spotted woodpeckers, and distinguished from each other by the spotted "greater," "medium," and "less;" though the comparatives must be restricted to themselves, and not in any way applied to the green one, though *major*, *medius*, and *minor*, have been used as their specific appellations.

Greater Spotted Woodpecker (P. major). This species is about nine inches long, a foot in the stretch of the wings, and weighs but half as much as the green one. The forehead, the sides of the head, the scapulars, a patch on each side of the neck, some of the wing coverts, the breast, the belly, and spots on the wings, and the tail feathers, except the two middle ones, are white. The occiput and vent feathers are dull greyish red, and all the rest of the plumage black. The female has no red on the head; and the young males have the red before the black on the head, while the mature males have them placed the other way. This is a hardy and active bird, residing more in cold situations, and in pine forests, than the former species; and as pines, from the turpentine they contain, have rarely insects so deep in the timber of them as deciduous trees have, this bird is not quite so exclusively a woodpecker as the other, but ranges more, and is more miscellaneous in its feeding. At one season, however, the cambium between the wood and the bark of the pine is remarkably sweet, and liable to be very seriously attacked by the larvæ of beetles. It is the same

with the outermost layer of the wood, when the tree begins to decay; for it should seem that this layer contains little if any turpentine; and therefore, if the trees stand too long, the insects marble over this part, by eating tracts in it, and the bark soon comes off in large patches, the rain gets into the wood and the tree falls. This catastrophe is in part prevented by the spotted woodpeckers. The females of these, like those of the former, make their nest in the holes of trees; the eggs are from four to six, and of a white colour. The young are as difficult to tame as those of the former, and there is certainly not more inducement to tame them. Woodpeckers of all sorts are strictly birds of the wild forests, very useful in their particular vocation there, but of no use whatever on cultivated grounds, or near cultivated habitations.

Medium Spotted Woodpecker (P. medius). This species differs but little from the former, except in size, in which it is inferior, and in having the bill more slender and sharper at the point. It is found in nearly the same situations with the larger spotted ones, but not so plentifully; and it is said to be less wild in its disposition. It is doubtful, however, whether the variation between them is sufficient to constitute a specific difference, and whether they ought not to be considered as one and the same species, accidentally varied in size.

Less Spotted Woodpecker (P. minor). This is a very small bird as compared with the others, being only five inches and a half in total length, of which two and a half are occupied by the bill and tail, leaving only three for the body. Its back is white, with cross bars of black; the rump white, the upper neck behind black; the top of the head crimson, and the under part reddish grey, of a pale shade, and streaked by black lines on the flanks. It is a very pretty little bird, and exceedingly active in its habits; but, as a British bird, it is rare and local; and, as a European bird altogether it has quite a different geographical distribution from the larger woodpeckers of the north. As a British bird this species is found only in the south and west of England; whereas the other one belongs rather to the west of Scotland. In taking a topographical estimate of the three species, which we have enumerated as British, we should be disposed to say that the green woodpecker is a forest bird of the richer parts of the country generally—that the larger spotted one is a mountaineer—and that the smaller one is a more delicate bird, and confined to the dry and warm districts.

In Europe it is probable that there are some others of larger dimensions than even these; and a black one is mentioned, which is four inches longer than the green, being seventeen inches in length, and weighing nearly double the weight of the green one. Its general colour is black, with the crown of the head scarlet, though this distribution of the colours is said to be not altogether constant. Some instances are mentioned of its having been shot in the west of England as a stray, but we are not sure that they are well authenticated. The bird belongs to a more easterly locality, is more powerful on the wing, and more a bird of wild nature and wild places than the others. It comes into Germany both by the line of the forests to the south and east of the Baltic, and by that of those in the valley of the Danube; though it is rare in France, or anywhere to the westward of the Rhine. Altogether, it is to be looked upon as a

Siberian bird, or a bird of the confines between Europe and Asia, rather than as a European bird.

We regret that our limits will not allow us to go somewhat more at length into the geographical distribution of European woodpeckers; because the natural history of woodpeckers involves the natural history of forests, and this again involves much of the relative physical geography of countries as compared with each other, and their relative aptitude for being improved by man. This last is the great practical gist of all rational natural history; and if it is not kept in view, all that can be said is really not much better than an idle tale.

The centre of Europe seems most adapted to the green woodpecker, and it takes most abundantly the line of the deciduous forests, where the sap of the trees is sweet and kindly, and they are in consequence subject to the attacks of larvæ. The spotted ones more affect the pine forests, whether of the north, the Carpathian mountains, or the Alps and Pyrenees; but they have not been traced in a manner sufficiently continuous for giving much of absolute certainty to even their geographical distribution; though, were this done, they might be made a sort of index or artificial memory to a great deal of knowledge of a most valuable description.

At the north-east, Europe passes gradually into the character of Asia; and hence we may conclude that the forest-birds of the northern parts of both are nearly the same. In central Asia it is difficult to trace the general geography of any animal; and it is just as difficult to connect Asia, northward of the Himalaya mountains, with Asia to the southward of the same. We must therefore restrict our observations to the mere naming of one or two of the Asiatic species of woodpeckers. On the continent of India, whether eastward or westward of the Bay of Bengal, they do not appear to be very numerous; and, indeed, we could not expect it, because, over many parts of India Proper at least, the wastes are covered with bamboo jungles, and not with trees fitted for the pasture of numerous woodpeckers. The ones in the south of continental Asia are also generally of small size, not so small as the little spotted woodpecker of Europe, but smaller than any other of the European ones.

Green-crested Woodpecker (P. chloropus) is an Indian species, measuring about eight inches in length. The upper parts of its body are green; the hind head is furnished with a crest of green and yellow, and there are some lines or markings of yellow surrounding the eyes; the coverts of the wings are spotted with yellowish white; the throat and fore neck greenish, the under parts marked with zig-zag lines of green and white; and the bill and naked parts of the feet brown.

Bengal Woodpecker (P. Bengalensis). This is of the same size, and belongs to the same country, as the former, but the markings of its colours are very different. The upper part is black; the top of the head is mottled with a number of white spots; the crest, the middle of the back, and part of the wing-coverts, are bright red; the quills are brown, mottled with white; the tail-feathers blackish brown; the throat and breast brownish, with darker mottlings of the same; the bill is bluish grey, and the feet brown.

The wooded parts of Java, and the other isles of the Sunda group, which abound in forests, contain a number of species of woodpeckers, but they possess

little interest beyond the mere enumeration of their colours. We shall therefore only mention one or two.

Philippine Woodpecker (P. Philippinarum) is a native of the group of islands whose name it bears, and measures about eleven inches in length. It is green and brown on the upper part, with some pale red on the head; the wing-coverts are yellowish red; the rump and tail-coverts bright carmine red; the under parts white, mottled with black; and the bill and feet black.

Malay Woodpecker (P. Malayensis) is about six inches long. Its general colours on the upper part are reddish grey and brown, and the under parts reddish white and reddish yellow.

Short-tailed Woodpecker (P. brachyurus). This is a native of Java, and about eight inches in length. It is dull brownish red, streaked with black on the upper part; the hind head is furnished with a very long crest; the under parts are reddish brown, mottled with black; and the tail is very short.

What we have enumerated must suffice as a specimen of the woodpeckers of southern Asia and the Asiatic Isles. The African ones are not so numerous; but we shall mention one or two.

Cape Woodpecker (P. aurantius). This is described as being of southern Africa, and it measures ten inches and a half in length. The upper parts are orange-yellow; the rump and upper tail coverts blackish, as are also the hind neck, the sides of the neck, and the cheeks; the top of the head is red, bordered by a white stripe on each side; the wing coverts are brownish-black on the small ones, and olive-green with golden reflections on the large; the quills and tail feathers are black; the bill and feet bluish-ash.

Double-mustachied Woodpecker (P. mystacus). This is another species of southern Africa, measuring about nine inches. The upper parts are olive waved with yellow; the cheeks and throat are white; the mustachios and front black, the latter dotted with red, and the hind head is red; the quills and tail feathers are brown, mottled with yellow on the webs, and have golden yellow shafts; the front of the neck is white, mottled with olive, the under parts brown, streaked with white, and the bill and feet brown.

There are one or two other species described as African; but as they differ from those mentioned in nothing but size and colour, it is unnecessary to allude to them; besides, in many of the species from southern Africa, it is not very easy to decide whether they are birds of that country, or brought from places farther to the east and north. It is also to be borne in mind, that the forests of India, of the eastern isles, and of great part of Africa, are not very decidedly woodpeckers' forests, and that the birds are consequently of inferior importance in the history of nature there, than they are in places where they are more characteristic.

When we turn our attention to America, especially to North America, we find the situation of things very much changed, and the woodpeckers very numerous and highly interesting. In this part of the world, too, we have the advantage of Wilson's description of their manners, as they were observed by himself in their native woods; whereas from the south and east we have nothing but dry details of colour. North America is indeed more of a woodpecker's country than any other now to be met with

on the face of the earth; and their historian has thrown a very high degree of interest over the labours and services performed and rendered by the American woodpeckers. We shall glance at the principal species.

Ivory-billed Woodpecker (P. principalis). Wilson gives Linnæus credit for the descriptive nature of this specific name, the bird in question being the prince of the whole genus. His powerful bill is of polished ivory, and his splendid crest is carmine-red, giving him a commanding aspect, and his manners correspond. "His manners," says Wilson, "have also a dignity in them superior to the common herd of woodpeckers. Trees, shrubberies, orchards, rails, fence-posts, and old prostrate logs, are alike interesting to those in their humble and indefatigable search for prey; but the royal hunter now before us scorns the humility of such situations, and seeks the most towering trees of the forests, seeming particularly attached to those prodigious cypress swamps, whose crowded giant sons stretch their bare and blasted, or moss-hung arms midway to the skies. In these almost inaccessible recesses, amid ruinous piles of impending timber, his trumpet-like note and loud strokes resound through the savage wilds, of which he seems the sole lord and inhabitant. Wherever he frequents, he leaves numerous monuments of his industry behind him. We there see enormous pine-trees, with cart-loads of bark lying around their roots, and the chips of the trunk itself in such quantities, as to suggest the idea that half a dozen of axe-men had been at work for the whole morning. The body of the tree is also disfigured with such numerous and so large excavations, that one can hardly believe the whole to be the work of a woodpecker."

Wilson, however, takes the proper view of this most active and energetic bird, and shows that he is a preserver and not a destroyer. "The sound and healthy tree is the least object of his attention. The diseased, infested with insects, and hastening to putrefaction, are his favourites; there, the deadly crawling enemy have formed a lodgment between the bark and tender wood, to drink up the vital part of the tree. It is the ravages of these vermin which the intelligent proprietor of the forest deploras, as the sole perpetrators of the destruction of his timber. Would it be believed that the larvæ of an insect, or fly, no larger than a grain of rice, should silently and in one season destroy some thousand acres of pine-trees, many of them from two to three feet in diameter, and a hundred and fifty feet high? Yet, whoever passes along the high road from Georgetown to Charlestown in South Carolina, about twenty miles from the former place, can have striking and melancholy proofs of this fact. In some places the whole woods, as far as you can see around you, are dead, stripped of the bark, their wintry-looking arms and bare trunks bleaching in the sun, and tumbling in ruins before every blast, presenting a frightful picture of desolation."

This glowing description by Wilson of the havoc which insects commit in the American forests, shows in the most forcible manner the vast advantage which such forests derive from the labours of the woodpeckers in keeping down the numbers of those ruthless destroyers. There have been nearly parallel cases in some of the pine forests of Europe; and it is by no means impossible that the ravages of insects were the chief means of destroying those extensive

forests which once thickly covered the Grampians and other hills of Scotland, and the quality of the remains of which show how exceedingly valuable the timber of those woods would have been, had it been still remaining to be applied to the purposes of the arts. Not many years ago a large extent of the Hartz in Germany was denuded of its timber by insects in the course of a very short time; and the labours of those destructive creatures proceed so rapidly, and are so perfectly beyond every means of human care, that the people even of a country which is supported almost exclusively by its timber, would have nothing left but to stand still and mourn the ruin. Nor would it require more than a single season to destroy every pine-tree in the northern zone of the world, if the mischief were not prevented by woodpeckers and other insect-feeding birds.

The insect plagues defy all human prevention and resistance; and though the individual creatures seem insignificant, their powers are multiplied up, by the countless myriads of their numbers, till they are not only beyond arithmetic, but absolutely beyond conception. In their attacks upon a forest, too, especially upon a forest of pines, which do not produce suckers at the roots, but finally perish, when the terminal buds are destroyed, the destruction is complete; and not a tree of the same species springs again in the same situation. In building, for many parts of ships, and for various other purposes of the most useful nature, the pine is more valuable than any tree in the forest; and, therefore, it is impossible not to regard it as a special instance of the Creator's goodness, that the woodpeckers are specially set to watch over and preserve the pine forests, where the enemy is always in the bud, the cambium, or the newly-formed wood, and not external upon the leaf, or tented up in it so as to be accessible to the slender-billed birds, which take the chief care of deciduous trees. The bill of no such bird can reach the destroyer in the pine, or in the dead tree, after the bark is gone; and it is because of this that the beautifully constructed and powerful bill of the woodpecker is brought into requisition. It must not be supposed that the insects in a dead tree are harmless to the forest; for the fact is exactly the reverse. They pour their myriads upon the living trees till not one is left; and, therefore, whether the woodpecker applies himself to one kind of tree or another, his services are always of value.

The ivory-billed woodpecker is a large bird, as well as a handsome one. Its length is about twenty inches, and the stretch of its wings two feet and a half. The general colour is black, with a delicate reflection of green and greenish purple; the forehead is black, but the head is covered with a crest of rich and brilliant red; there are some white feathers over the nostrils, and the feathers of the crest are also mottled with ash colour, and then white near their bases; but as these mottlings are not seen, except when the crest is erected, it appears wholly of an intense red, when in a state of repose; the sides of the neck and the back are marked by two white lines, about an inch apart from each other, and extending nearly to the rump; the first five quills are wholly black, but part of the secondaries and their coverts are white, and this has procured for the bird the name of the white-backed woodpecker; the tail is black, and oval at the extremity, by the lateral

feathers being three inches shorter than the middle ones; the coverts and shafts of those tail feathers are particularly strong, and the stiff webs turned downward, so as to form a hollow on the under side of each. By this means the tail acts with much better effect, in supporting the bird during its labours on the trees. The neck is long, and capable of very powerful motion; and perhaps there is no instrument among the whole feathered race equal to the bill, either in materials or mechanical structure. It is an inch broad at the base; it tapers in those curves which give the greatest degree of strength and stiffness combined; the ridges which strengthen it make it as strong as if it were twice as heavy, and consequently twice as fatiguing to the bird; and the substance of it combines the toughness of horn and the hardness of ivory; the legs are short, but very stout in the tarsi; the length is about an inch and a quarter, and the outer toe is nearly the same; the claws are strong, semicircular in their form, and both feet and claws are leaden blue; the female is rather less than the male, and wants the fine red crest, but in other respects her colours are nearly the same; the last half inch of the tongue is beset with barbs, and the tip of it is nearly as hard as the bill, so that it can draw larvæ out of their holes, much in the same manner as a shot is drawn by means of a ramrod. All woodpeckers have simple membranous stomachs, incapable of reducing hard vegetable matter; and those of all the individuals of this species which Wilson examined, had them well loaded with those large larvæ, two or three inches in length, whose ravages are so destructive to the trees, especially in the warmer parts of the United States.

This, which is by far the most interesting of all the woodpeckers, is not generally distributed indiscriminately over the United States, but is rather restricted to those southerly ones in which insects are so destructive. Virginia is their northern limit on the Atlantic side of the country, though they perhaps range a little farther north in the central valley. They do not migrate, but remain on the same grounds all the year, nestling in the holes of trees, and laying four or five eggs in a hatch, the young from which appear about the middle of June.

The habits of these birds in their breeding places have not been very carefully observed; and the observation of them is attended with some difficulty and labour, in consequence both of the situations in which they build, and of the places of the nests. In the Carolinas, where they are understood to be more numerous than in any other part of the United States, they build in the cyder swamps, that is, in those marshes which are so thickly overgrown with the junipers, which are called cyders in North America, that it is impossible so to explore them, as to ascertain what they contain, or what goes on in them. Such places are highly pestilent in the warm weather, and therefore few have the hardihood to enter them; nor is there any doubt that Wilson shortened his life by his zeal in exploring those unwholesome places, as he was only forty-one years of age when the world was deprived of his delightful, and, in some respects, inestimable labours. The nests are made in the thick trunks of the cyders, at a considerable elevation above the marsh; and it is not necessary that the nesting tree should be absolutely hollow, for the pair of birds working alternately with their powerful bills, can in brief space excavate the solid wood to the extent

which they require. They enter by a sort of winding passage, and then they work downwards to the nest, which must be of pretty large dimensions, and their depth into the wood is never less than two feet, and sometimes as much as five.

Their efficiency with the bill is proved by an anecdote which Wilson relates of a bird that he wounded in the wing, and then contrived to capture, not far from Wilmington in Carolina; but we must allow him to tell his own story. After he had got possession of the bird, "it uttered a loudly reiterated, and most piteous note, exactly resembling the violent crying of a young child; which terrified my horse so as nearly to cost me my life. It was distressing to hear it. I carried it with me in the chair, under cover, to Wilmington. In passing through the streets, its affecting cries surprised every one within hearing, particularly the females, who hurried to the doors and windows with looks of alarm and anxiety. I drove on, and on arriving at the piazza of the hotel where I intended to put up, the landlord came forward and a number of other persons who happened to be there, all equally alarmed at what they heard. This was greatly increased by my asking whether he could furnish me with accommodations for myself and my baby. The man looked blank and foolish, while the others stared with still greater astonishment. After diverting myself for a minute or two at their expense, I drew my woodpecker from under the cover, and a general laugh took place. I took him up stairs and locked him up in my room, while I went to see my horse taken care of. In less than an hour I returned, and, on opening the door he set up the same distressing shout, which now appeared to proceed from grief that he had been discovered in his attempts at escape. He had mounted along the edge of the window, nearly as high as the ceiling, a little below which he had begun to break through. The bed was covered with large pieces of plaster, the lath was exposed for at least fifteen inches square, and a hole large enough to admit the fist opened, to the weather boards; so that in less than another hour he would certainly have succeeded in making his way through. I now tied a string round his leg, and, fastening it to the table, again left him. I wished to preserve his life, and had gone off in search of suitable food for him. As I reascended the stairs, I heard him again hard at work, and on entering had the mortification to perceive that he had almost entirely ruined the mahogany table to which he was fastened, on which he had wreaked his whole vengeance. While engaged in taking a drawing, he cut me severely in several places, and, on the whole, displayed such a noble and unconquerable spirit that I was frequently tempted to restore him to his native woods. He lived with me nearly three days, but refused all sustenance, and I witnessed his death with regret." This anecdote is highly characteristic of this finest of all woodpeckers; and it is just as characteristic of the naturalist as of the bird. With it we must close our remarks, and shall advert to the others more briefly, only noticing farther, that it does not appear that any species, at all resembling this in power and spirit, is found in any other part of the world than North America.

Pileated Woodpecker (P. pileatus). This bird is rather smaller than the former, but still it is one which ranges much farther to the north; and endures all the varied climates from the southern States to the middle of Canada. The length of this one is a

foot and a half, and the stretch of the wings two feet four; dull brownish black is the general colour; but there is a pointed cap of bright scarlet on the head, and two mustachios of the same colour appended to the lower mandible. The chin is white; and the white markings on the neck, back, and wings, are nearly the same. The feet are leaden blue, and the eyes golden yellow as in the former species; but the bill is a different colour, being bluish black in the greater part of the length, and bluish white at the point. This species is sometimes accused of attacking the plantations, especially those of Indian corn; but it does not appear that there is the slightest ground for the accusation. The birds build in holes of trees; the eggs are about six, of a brilliant white colour, and it is understood that there are two broods in the year. They are therefore much more prolific birds than the ivory-billed woodpeckers; and they seem to be rather more discursive as well as more generally distributed. They are exceedingly active birds, always in motion of some description or other.

Gold-winged Woodpecker (P. auratus). This is a smaller species than any of the two preceding ones, more gay in its plumage, and a little different in its manners. In the colder parts of the United States these birds are migratory, but in the milder parts they are permanently resident. The total length is about a foot, and the stretch of the wings twenty inches; the back, and upper sides of the wings, are rich brown streaked with black; the top of the head smoke-grey; and the cheeks with the space round the eyes crimson brown; there is a black stripe like a mustachio from each angle of the gape; the throat and chin are fawn, passing into bluish grey on the lower part; on the hind head there is a crescent spot of deep but pure red, and an intense and larger one of black on the breast; the rest of the under parts have a yellowish tinge, but mottled with bright black spots; the lower sides of the wings and tail, and the shafts of all the larger feathers, are rich golden yellow; and the rump and tail coverts are white. The markings of this bird are exceedingly beautiful as well as striking, but they are too varied for minute description. Though they appear to be migratory in some places, they winter far to the north, appear to be remarkably hardy, and are said to resort to wild berries, when the insect supply of the trees begins to fail.

Red-headed Woodpecker (P. erythrocephalus). This is an exceedingly abundant bird in North America, and stands accused of being a great plunderer of small fruits in orchards, and also a thief on the Indian corn. So notorious are those propensities on the part of the bird, and so persevering is it in the practice of them, that a price is set on its head. The wisdom of this is however very doubtful; for it is only at one season of the year that these birds live upon fruits, and they are busied all the other parts in looking after the trees and keeping them clear of insects. Now in all countries fruit trees are more liable to insect ravages than trees of almost any other description, because their juices are generally speaking sweeter, and their vigorous action in most of the species begins more early in the season. The suspending of this action by the reverses of the weather which are so common in the spring, is particularly favourable to the production of insect larvæ, both on the leaves of the tree, and in and under the bark. The early season in most parts of the United States, is remarkable for the great and rapid variations of the weather. North America is a country which literally

swarms with insects; and therefore, if there be one portion of the world where birds to clear the fruit-trees of insects are especially required, unquestionably that is the United States. As this bird comes more about houses and orchards than most of the species, it is obviously the most useful bird there; and therefore it deserves protection instead of persecution.

In many parts of the United States these woodpeckers shift their quarters with the season, though they move pretty far north in the summer. They appear in the middle States about the end of April, and leave them in October. They begin to build their nests about the middle of May; and, like the others of the genus, they construct these in the trunk or large branches of trees, generally speaking, without any other materials than what the tree furnishes, which being smoothed down to the proper shape forms a bed for the eggs. The eggs are six in number, of a white colour, and marked at the greater end with reddish spots. The young are hatched towards the end of June; for the first season the head and neck of the young birds are blackish grey; which circumstance has caused some European writers to mistake them for females. The white of the young is also spotted with black; but in the succeeding spring they recover their perfect plumage; when the only difference between the male and the female is that the colours of the latter are not quite so bright, and that it is rather smaller than the male bird: the head and neck of both are deep scarlet; the bill is strong, light blue at the base, and black towards the point; the back, the primaries, the wing coverts, and the tail, are black, shaded with steel blue; the lower part of the back, the rump, the secondaries, and the whole under parts from the breast downward, are white; the feet and legs are bluish green; and the claws are light blue; round the eye there is a narrow stripe of naked skin of a dusky colour; the iris is dark hazel. The length of the bird from the bill to the tip of the tail is about nine inches; and the stretch of the wings seventeen. Like the rest of the genus, this bird takes great pains to place her young in an elevated situation on the tree, beyond the reach of enemies; but notwithstanding this, there is one deadly foe, against whose depredations these precautions are no security; namely, the black snake, which though armed with no poisonous fang, is a great destroyer of eggs and young birds. This snake winds up the trunk of the tree, enters the nest, eats the young or the eggs as it happens, and coils himself up to doze where he has committed his depredation. Wilson says, "the eager school-boy, after hazarding his neck to reach the woodpecker's hole, at the triumphant moment when he thinks the nestlings his own, and strips his arm, launching it down into the cavity, and grasping what he conceives to be the callow young, starts with horror at the sight of a hideous snake, and almost drops from his giddy pinnacle, retreating down the tree with terror and precipitation."

Red-bellied Woodpecker (P. Carolinus). This species is a very little larger than the red-headed one; and it is more woodland in its manners; seldom appearing in orchards or near houses, but keeping to the tall trees in the close forests. It is a restless and noisy bird, and very active in examining the trees; and perhaps it is a more expert climber than most of its congeners. The birds build high, in the hollow left by the stump of a broken branch, or in an excavation made by the birds themselves, if they

cannot find a natural hole fitted for that purpose. They pair earlier than the preceding genus, and the young climb about the branches, and often fall to the ground, or are captured by those birds of prey which are in the habit of beating over the forests during the time when the tree birds have their nests and their young. It is understood that they have two broods in the course of the year, and there are generally five eggs in each hatch; but this more abundant production than in many of the woodpeckers, is in so far counterbalanced by the casualties to which we have alluded. The length is ten inches, and the stretch of the wings seventeen. The bill is an inch and a half long, strong and of a bluish colour. The nostrils are covered with tufts of brown hairs which curl forward. The feathers on the forehead form a sort of projecting cap, and are of a dull reddish yellow. Behind these, along the upper part of the head, down the back of the head, and spreading down to the shoulders, is golden red, of the most brilliant metallic gloss. The rest of the back is black, with cross bars of white, and the rump is white with some markings of black. The wings are black; but the lesser coverts have white tips, and the quills crossed with lines of white. The cheeks and sides of the neck are pale buff, gradually deepening into ash colour, and again passing into blood-red on the belly. Some of the small feathers are remarkably beautiful in their markings, but they are too minute for general description. These beautiful birds are found in the West Indies as well as in North America; and in all places where they are found, they are especial conservers of forest trees, and at the same time highly ornamental.

Yellow-bellied Woodpecker (P. Varius). This species is still smaller than the preceding one, being eight inches in length, and fifteen in the extent of the wings. The crown of the head is rich scarlet, bordered at each side with black, and the feathers are a little produced, forming an erectile but not very long crest. From near the gape a narrow stripe of white descends on each side, bending round, and gradually passing into the yellowish white on the breast. The enclosed portion of the throat is rich scarlet bordered with black, the same as the feathers on the crown. The back is dusky yellow waved and dotted with black, the wings are black, and the belly yellow. The minor markings upon the bird are beautiful, but numerous and intricate. It appears that the habits of these birds are somewhat different from those of the typical woodpeckers; for they have muscular stomachs, and swallow gravel apparently for the purpose of assisting in the trituration of their food, which food appears to consist more of full grown beetles than of larvae, though the birds collect the greater portion of it from trees, especially fruit trees in orchards in places where such are to be found.

Hairy Woodpecker (P. Villosus). The habits of this bird pretty much resemble those of the species last mentioned. In winter and early spring, it is much in the inhabited grounds, and clears trees, posts, and all wooden erections from the depredations of insects. These last services are of no inconsiderable importance in a country like America, where so many dwelling houses and other buildings are constructed of wood. Insects destroy these to a very great extent; and therefore the woodpeckers which come about the wooden buildings and fences,

ought to be favoured birds with the inhabitants. About the month of May they retire farther into the woods; though some remain and build in holes of the fruit trees. The eggs are five in number and pure white; the body is nine inches in length, and fifteen in the stretch of the wings. The fore part of the head is black, and the nape scarlet; a black line passes across the eye, and increases in breadth as it proceeds toward the back, where the whole is black except a broad lateral stripe of white. The feathers on this part consist of small shafts like hairs, without any webs to them; and it is on this account that the bird is called hairy. There are also hair-like feathers of considerable length at the bases of both mandibles. The wings are black, variously spotted with white; and the tail is black in the middle and white at the edges. All the under parts are white. The female has no red on the head; and the under part is mottled with brownish.

This is understood to be a discursive bird, at least to a considerable extent; for a straggling specimen or two of it are reported to have made their appearance in England; and either it, or a species very similar, has been found in the eastern parts of Siberia. That an American woodpecker should find its way to Siberia is by no means unlikely, because the distance of the two continents is but small. Coming to England is, however, a different matter; and it is a known habit of woodpeckers never to carry on their migrations to any very great extent, or by long flights; their style of flying is very ill adapted for such a purpose. They leap through the air, ascending, and then descending a considerable way at each leap; and flying in this manner is of course far more fatiguing than smooth flight, in which no lifting of the centre of gravity is required. The leaping flight of the woodpeckers is well adapted to their general action in the wood, as their movements on the wing there consist chiefly of ascents and descents. We believe too that few or no instances have ever occurred of the woodpecker being seen flying higher than the tops of the trees, and very seldom as high. Long migrations are always made by lofty flights, where the birds are above the disturbances of the lower atmosphere, and get the advantage of those general currents of the upper air which assist them so much in their migrations. We are not of course disposed to question the authorities which mention the appearance of these birds in England; but it is rather a puzzling problem in animal mechanics to ascertain in what manner they performed their voyage.

Downy Woodpecker (P. pubescens). This species is very like the last-mentioned one in the markings of its colours, so like, indeed, that a description of them is hardly necessary. It is, however, much smaller, being only six inches and a half long, and about a foot in the stretch of the wings; but its diminutive size does not lessen its usefulness in the woods, and especially in the orchards.

This little woodpecker is a very diligent labourer in the last of these, and he goes about his work in a much more scientific manner than the larger ones. He takes the circumference of the tree in circles, working gradually round, and shifting a little higher after he has completed one circle. In this, however, he does not "girdle the trees," as it is called in America, but merely punches little holes about an inch or an inch and a half apart. These holes do no

injury to the tree, but rather, by reducing the action of the stem, tend to make it more productive of fruit. This is not the special labour of the woodpecker; for he takes an insect, of some kind or other, in some stage of its growth, out of each of these little holes. Had these insects remained, the tree would have been very speedily destroyed. But the other effect is perfectly consistent with the mode in which fruit-trees are kept in a vigorous state of production by skilful gardeners. The natural action of even a fruit-tree is principally in the promoting of its own vegetation; and hence, in order to increase the production of fruit, it becomes necessary to lessen not only the production of wood, but the tendency to produce it; and this is very frequently done by removing portions of the bark.

There are still several species of North American woodpeckers remaining unnoticed, and there are many species in South America. Enough, however, has been given as a specimen of those of the north, and we have endeavoured to give it with reference to their uses both in the forest and the orchard. The larger ones are chiefly met with in the first of these situations; and there is no doubt that, had it not been for them, the forests of many parts of North America would ere now have been gone. Nor are the small ones of less value in the orchard and about the farmhouse.

Of the manners of the South American ones, or the precise effect which they have upon the forests there, we know little. As the trees are different, the labours of the birds must be different; and they have many more assistants than their northern congeners.

There remain two genera of small birds, most of which have been, at one time or other, confounded with the woodpeckers. See the articles *PICUCULI* and *PICUMNUS*.

PIGEON (*Columba*, or rather perhaps *Columbidæ*, —The Pigeon family). The pigeon family, or *COLUMBIDÆ*, as we shall style them when we speak of them in general terms, are one of the most numerous, the most widely distributed, and in some respects the most interesting families of the feathered race. It is true that very many of them levy very extensive contributions upon the products of human labour, and none of them can be said to perform any very important service in return. They may be considered as among the greatest consumers of the fruits of the earth. They are all exclusively, or nearly so, vegetable feeders; all tribes of them are voracious feeders; and many of them congregate in flocks which are perfectly innumerable. It is true that the flesh of very many of them is good, rather abundant in quantity for the size of the birds, and somewhat racy in the flavour, though by some reckoned too stimulant for being healthy.

Notwithstanding their numbers, their general distribution, their beauty, and the proverbial kindness of their dispositions, which have been handed down from very remote antiquity, only one out of a great number of species, and indeed of genera, has yet been brought into subjection by man; and even this one is lodged and fed rather than domesticated. This one is the common pigeon-house pigeon, known as the rock-pigeon when in the wild state, and in that state abundant in several places of the clifly and caverned shores of the British islands. This one has indeed broken down into a great number of varieties, differing much from each other in appearance, and

called by different names, one of which at least, the carrier-pigeon, is employed in bearing messages to places very remote from each other. It is doubtful, however, whether, under any circumstances, the keeping of pigeons is a matter of economy; but that circumstance does not lessen their interest in the estimation of the naturalist who wishes to study them in their free state; and the domesticated one, including all its varieties, is a mere drop in the bucket as compared with those which are still to be found in wild nature.

With the exception of the polar zones, pigeons are found not only on every broad land, in all torrid and temperate latitudes, but in the remote isles of the sea. With the exception of comparatively a few, and these mostly in countries which hardly know any winter's cold, the whole of the family are birds of powerful wing, capable of remaining long in the air at a time, and thus continuing their flight over long distances.

In such countries as Europe, where the soil is in pretty general cultivation, and the winter is comparatively severe, they are not very numerous. In North America they are much more so in individuals, if not absolutely in species; and yet, latitude for latitude, the winters of North America are far more severe than those of Europe. But, in North America, they migrate with the seasons far more than they do in Europe. In Europe, too, the larger seeds of faded plants, and the small fruits, upon which pigeons are fond of feeding, are much less abundant than in America. In the former part of the world the greater part of the harvest of the year is gathered in by man, or by animals in which he takes an interest; while in America, so comparatively small an extent of the surface is peopled and cultivated, that the far greater part of the harvest of the year is left to be gathered in by the children of wild nature. In South America, and the intermediate islands, there are also many species; and the same is the case in Africa; though in neither of those countries does any one species appear to be so abundant in numbers as some of those in North America. A new character, however, begins to appear in some of them. The pigeons of the north, though many, indeed most of them, feed upon the ground, are all birds of powerful wing, and capable of shifting their localities if the state of the season shall deprive them of food. Pigeons of this character are also to be found in the southern parts of America and in Africa; but in these places there are others much less formed for flight, and therefore much more habitually upon the ground.

New Holland and the isles of the Pacific, including among those New Guinea and the Sunda Islands, and a portion at least of the south-east of Asia, might be considered as the grand head-quarters of the pigeons; and in those regions some of them are far more gay in their plumage, elegant in their forms, and splendid in all their characters, than in almost any other part of the world, though they are everywhere a handsome race of birds. Among those islands they are discurive, shifting from region to region with the monsoons, as these bring about at different times a supply of those wild fruits upon which they chiefly subsist. In the same islands and countries too, especially if they are of considerable breadth, there are also pigeons of less powerful flight, and better adapted for walking, which find their food chiefly on the ground, and

are rarely on the wing, except for low and short flights.

The *Columbidæ* were long considered as confined to the pigeons properly so called, and the turtles, or, as they were styled in popular language, doves and turtle doves. But as the birds of new lands began to be examined with attention, and species of forms, colours, and habits, very different from either of these two, began to be added to the collections and museums, the single genus *Columba*, to which the new ones were added when they were discovered, began to get cumbrous from its extent, and not very susceptible of correct generic definition, because a short summary of characters could not be so framed as to include the whole. This of course led to successive divisions of them; first into subgenera, then into genera, and ultimately into subfamilies and genera. The original method of having but one class was certainly imperfect and incorrect; and it could scarcely have been otherwise, because it could be founded only upon the species then known, and they have proved to be a very small fraction of the entire number. On the other hand, it is highly probable that some of the more recent arrangements have fallen into the opposite extreme. A few years ago there was an excessive, and as one might say an inordinate desire to multiply genera, and the same desire remains with many to the present time. Now this is a bar in the way of those who wish to learn natural history. It is desirable that every one, beginning with the classes of the animal kingdom, should pursue those classes downward through their orders and families, as far as the genera. Thus far may be regarded as the science of natural history, and as such ought to form part of every liberal education. Doing so, it ought to reach the general structure and habits of all the animals, their adaptations to climates and localities, and their uses in wild nature and to man. But it should stop there; and there ought not to be admitted into the system a single character as generic, for which a reason cannot be given. After this the matter is to be taken up by the professional, museum, or mechanical naturalist, whose business it is to describe every shade of appearance with the utmost accuracy, whether he understands any thing about the use of it or not. He is properly the collector and recorder of facts; and it belongs to men of more enlarged views, who are not fettered by petty details, to bring those facts within the philosophy of the science, in as far as they can be so brought.

We have stated briefly this distinction, because we think that, in the case of the family of birds under notice, as well as in other parts in the natural history of animals, there has been a tendency to mix up the mechanical details with the philosophy of the science, and thereby to vitiate the latter as a part of general education.

There is another point in which the natural history of the *Columbidæ* has been, and still remains, a little confused. This has arisen from pushing the doctrine of affinities a little too far. Pushing doctrines, which are hypothetical in their foundations, too far, is the cause of half the errors in every branch of knowledge; and yet there is nothing more difficult to be avoided. A man takes up the hypothesis fondly, makes it his own, and dotes upon it, until it spoils his perception for every thing else. Or, if we may so express it, the man runs away with the idea, and continues run-

ning till he is out of breath, and can run no more ; and then the idea whips him up, and runs off with him so fast and so far, that his head is turned, and he loses his senses.

Upon this principle of the overstretching of affinities, the *Columbidae* have often been regarded as a division of the *Gallinidae*, and described as such. Cuvier says that they form an easy transition from his great order *Passeres* to the *Gallinidae*, and he includes them in his order *Gallinacea*. But every one knows that Cuvier was as modest as he was mighty, and wished to make the fewest changes possible upon the established nomenclature of animals ; and though he speaks of a transition or passage, he certainly does not imply what is called an affinity, either with the one or with the other. In avoiding the use of this term, Cuvier showed his usual science and sagacity ; for in the two great foundations upon which alone a natural classification of animals, that is, a classification useful as an instrument in the study of nature generally, can be founded, there is little or no resemblance between the pigeon family and the poultry family. These two grand points are, how the animals feed, and how they propagate ? The first is the one which goes directly to connect them with nature ; because it is the fact of its consuming the surplus of certain substances which makes an animal useful in the general system of nature ; and the second is useful only as it continues the animal to consume this surplus through successive generations. Now the pigeons are, as has been already hinted, nearly, if not exclusively, vegetable feeders, and feeders chiefly upon seeds or fruits. Many of the poultry, again, are of an omnivorous character, and some subsist, in great part, upon leaves.

The distinctions in respect of reproduction are still greater. The poultry tribe are, we believe, without a single exception, polygamous. The males fight battles of gallantry ; but little or no affection subsists between them and the females ; they take no concern whatever in the incubation, and some of them are prone to devour the eggs, if these are not concealed from them. The females also have large broods, and some of them very large ; and though they are attentive mothers, and proverbially brave in the defence of their young, they never, in any instance, put food into their mouths with the bill, nor are there, we believe, any instances in which the young remain in the nest after they have broken the shell.

The pigeons, on the other hand, are, in every species of which the habits are known, strictly monogamous. The males fight no battles of gallantry, and the affection which subsists between the pair is so great, that doves have, from the earliest times, been regarded as the appropriate emblems, not only of love, but of all the peaceful and kindly affections. The male alternates with the female in the labour of incubation ; the brood is, generally speaking, a single pair ; they remain for some time in the nest, and they are fed there by both parents, not only with the bill, but from the stomach, and with the food prepared by solution and combination with a stomachic fluid. This feeding is continued not only until the young leave the nest, but for some time afterwards.

In these last circumstances there seem to be very substantial grounds for establishing a general structural distinction between pigeons and poultry. In every department of the feathered tribes it is found that

the attention which the young receive after they break the shell is prolonged in proportion as the plumage, and especially the feathers of flight, are to be of a more perfect character, and consequently brought more into use, for in nature the use and the quality of that which is used always agree with each other. Now, any one who chooses to set a pigeon and one of the poultry tribe together, taking any of the numerous species of either, will not fail to observe, that there is a striking difference in the texture and gloss of the plumage. On the pigeon it is remarkably smooth and compact in the clothing feathers, and equally firm in the feathers of flight, and in the typical pigeons there is not a single supplementary or superfluous feather, nor are there many such upon the others, unless it be a light crest upon the head. Among the poultry there are differences, no doubt ; but the plumage of all is comparatively loose and soft, and a considerable number are furnished with supplemental feathers, which, instead of assisting in their flight, must impede their progress. No doubt there is some similarity in the *sterna* ; but it is confined to the posterior angles, and consists in there being two notches in each, and the keel of the *sterna* is much more developed and the articulation, of the wing much better supported in the pigeon than in the other.

Those pigeons indeed, which feed chiefly upon the ground, and never range far in quest of their food at one flight, are inferior in their organs of flight to what may be called the air pigeons ; but their clothing plumage still retains the pigeon character, and they do not display that toil and flutter which are so conspicuous in the others.

If we look at the action of the birds in the air, we shall soon perceive the difference in this respect ; and perhaps the comparison could not be made upon a fairer average of the two families than upon the rock pigeon in its wild state and the common partridge.

Whoever has visited those bold and caverned cliffs where rock pigeons dwell, may have seen them out when the wind was so strong as that he required to guard both his head and his feet, to prevent him from losing his hat at the one extremity, and from staggering or tumbling through instability at the other. Not only are they out in tolerably fresh breezes, but they are quite at home in them, and wheel and double so as to fly upon all winds without turning a feather. But we believe nobody ever saw partridges rise naturally during a stiff breeze. They make toil and flutter enough on a calm autumnal day ; and if they were to try upon a stiff breeze, a point or two abaft the beam, every windward feather would be up, and they would be compelled to drop helpless to the ground, and seek safety in their legs, from their wings being unfitted for the weather.

We have instituted these comparisons, both general and particular, in order to prevent the general reader from being misled by some of the modern works which profess to be accurate, and are sold at an easy price, by attempting to demonstrate for him a proposition which ought to have required no demonstration, and of which the enunciation is quite a facsimile of Katerfelto's well-known positive and negative definition of lightning and thunder. It might run thus : First, positively, a pigeon is a pigeon, and a pullet is a pullet ; second, negatively, a pigeon is not a pullet, and a pullet is not a pigeon. We think

F F

nobody will dispute this, and therefore we at once subjoin the Q. E. D., which is understood to seal the matter in every clear and satisfactory demonstration of truth. Having done this, we shall briefly advert to the *Columbidæ* in their proper character as a family, in their more obvious subdivisions, and in one or two of the most interesting species of each.

The general characters are: the bill arched, the nostrils pierced in a large membranous space, and each covered with a cartilaginous scale; this membrane is often enlarged to a considerable size at the base of the bill; the sternum consists of firm bone, but is deeply and doubly notched in the posterior part, though different in different species; the crop is very large, and capable of great dilatation; and some of the varieties of the tame pigeon have the power of distending it to a very great size by inflating it with air: the larynx at the bronchial, or lower extremity of the windpipe, has only a single muscle, so that they have little or no voice except a sort of murmuring coo, which, however, is generally soft and pleasant, though melancholy, and some of them can give it a little modulation as to time, though scarcely any in pitch; the feet have three toes to the front, but they have no connecting membrane at the base any more produced than it is on the sides of the toes, and the hind toe is articulated on the same level with the three front ones; there is thus but little spring in the foot, and they cannot run fast, though many of them can walk well; their wings and style of flight vary considerably, according to the mode of life for which they are adapted; but whether their flights be long or short, high or low, they may all be said to be good flyers. We have already alluded to their monogamy and small brood, but the brood is repeated in the course of the year, and thus they are upon the whole very prolific birds. Their nests are not made with the greatest care, but they are much superior to those of the *Gallinidæ*, which, generally speaking, do not deserve the name of nests at all. They are placed in trees, or in the holes of rocks; the rock ones in general build high, and the tree ones in places where there is close foliage. Such are the leading characters which apply to the whole; and we shall now advert to the greater divisions.

Cuvier may be regarded as still the best authority in this respect, because, though not nearly so minute as that of others, his division is sufficient to reach a general character in each of the three genera into which he divides the family. We shall, however, reverse the order in which he takes these genera; because, while he places those first which bear the closest resemblance to the *Gallinidæ* in some habits, we shall consider them in their own characters as a distinct family, and, therefore, we shall place those first which have the most striking and decided character. Taking them in this order, the three genera will be: first, *Strong-billed Pigeons*, or those which subsist chiefly upon the fruits of trees and shrubs; secondly, *Common Pigeons*, or those which, though they are still discursive flyers, live more upon the seeds of herbaceous plants, which they pick either from the plants themselves, or from the ground; and, thirdly, *Ground Pigeons*, or those which reside chiefly upon the ground, and take only short flights, though they also nestle in trees and shrubs, only at smaller elevations than the others.

In each of these genera there are great diversities, and they have accordingly been divided and sub-

divided; but, for the reasons already assigned, we shall not go into the particulars of those divisions.

STRONG-BILLED PIGEONS (*Finago*). The distinguishing characters of these are: the bill stout, very hard in the distal half, but flexible in the basal, strong in its substance, arched in the outline of both mandibles, hooked, and very sharp at the tip of the upper one, and compressed in its whole length; their tarsi are short and clothed with feathers, and their feet are adapted for perching on trees, and not so much for walking on the ground; in order to give them a firmer footing on the branches, the toes are margined by a pretty extensive membrane; the external front toe is the largest, as in climbers and tree birds generally; and the claws are strong, sharp, and very much hooked. All these characters are possessed in a greater degree by some of them, and in a less degree by others; but still they are sufficient in the whole to bring them together, if not as a perfectly-defined genus, at least as a group very distinct from the other two divisions of the family.

Their appearances and manners, and even their principal locality, may be said also to be different; and though there are other pigeons along with them, they are the characteristic pigeons of the south-east, of a part of the south of Asia, of the Eastern Isles, of the Isles of the Pacific, of New Holland, and also of Africa, but chiefly, we believe, of the eastern half of it. They are altogether forest birds, and inhabit the tall trees, living upon fruits, which their powerful wings, the firm clutch of their feet, the hard texture of their bills, and their general strength, enable them easily to reach and secure. Their colours are in general very rich and beautifully marked; green and yellow are the predominating ones in almost every species; but many of them have also purple, brown, red, and white, though the latter rather sparingly, and some have a sort of cinnamon-brown and orange-red as the predominating colours.

The whole of them are birds of powerful wing, and in general their wings are pointed, and in many the tails are long. Indeed, the form of the tail differs so much, that it cannot be admitted as a character of the genus taken as a whole, or even of those subdivisions which have been made of it. Though many of them migrate, their general habit may be said to be habitual residence in the close forests of those countries where they dwell, and we are not aware that any of them reside in a place where the trees are not evergreens, and capable of supplying some kind of nourishment at every season of the year. A considerable number of them have been for some time known to naturalists, and specimens are to be found in most collections of stuffed birds, while a great number of them are figured by Temminck, and some have been kept alive in Europe. Several species, however, are comparatively of recent discovery, and it is highly probable that future observation may discover many more. Their range being about seven thousand miles in longitude, and more than four thousand in latitude; besides being so extensive, their country, though all decidedly tropical, is much diversified in its character; and the retiring habits and colours of the birds render them not easily seen, although it were possible to beat the mighty forests of those parts of the world with the same case as a pheasant-grove or cover can be beat in England. When they are discovered indeed, it is, as is the case with pheasants at night, by the ear and not by the eye, for they coo away in

perfect security under the thick shade of the luxuriant foliage. Generally speaking, their flesh is dark-coloured and tough, not very well flavoured, and, therefore, they are not very eagerly sought after as game.

Pointed-tailed Pigeon (V. oxyura). This bird is a native of the Sunda Isles; and it is remarkable for the form of its tail, which is very long, stout, much wedge-shaped, and has the two central feathers much produced beyond the others. The general plumage is green, most brilliant on the neck and belly, and crossed on the breast by a broad band of orange red, which fades gradually into the green both ways; the lower part of the belly and the under tail-coverts (which, taken altogether, are lancet-shaped and very pointed) are yellow, blending gradually with the green on the body, but well defined on the tail-coverts, the under sides of the tail-feathers being blackish green at their bases, and pale grey at their tips; the quills are black, and, though the wings are long, they do not when closed reach much beyond the two lateral tail-feathers, which are not above one-third the length of the two middle ones; the bill is black at the base and yellow at the tip; the feet are bright reddish orange, and the tarsi are mottled with green feathers; the space surrounding the eyes red and pointed, both in the direction of the gape and backwards. This bird is abundant in Java and the other Sunda Isles; but it is not known what difference of habit results from the form of the tail, which is peculiar among the whole of the tribe; for though many of them have the tails much wedge-shaped, and some have them very long, this is the only one which has the two middle feathers so much longer than the rest. Length twelve inches.

Aromatic Pigeon (V. aromatica). Though this species is only about nine inches long, it is really larger in the body, in consequence of the comparative shortness of the tail. Altogether it is a stouter bird, apparently less formed for rapid flight, and its bill is particularly strong and hard; the upper part is purple brown, passing into sandy yellow of a greenish tinge, which is the uniform colour of all the under part, including the sides of the head as high as the eyes; but the colour is a little paler than the last: the colour of the upper part passes into greenish ash on the nape, greyish ash on the top of the head, and bluish ash on the front; the quills are black, and the coverts of the wings brown, each feather with a very distinct border of yellow; the rump and middle tail-feathers are green, and the lateral tail-feathers black and grey; the feet are red, with a tinge of orange, and the bill yellowish green. It is, however, subject to varieties of colour.

It is a very common bird, both in India and the eastern islands, and the spreading shade of the banyan or Indian fig is one of its favourite habitations. Every one knows that, according to the Indian superstitions, this is a sacred tree, and also that it has a peculiar habit of growth in sending down perpendicular fibres from the branches, which enter the ground and take root, until the tree has a vast number of trunks, and becomes a grove of no mean dimensions, all united by solid wood at the top, and thus proof against the most violent winds, at the same time that its foliage is so close, that scarcely a sun-beam can find its way through.

They are birds of mild and timid disposition, and, like most of the pigeons, they live socially, except during the breeding season, at which time each pair

retire to their own nesting-place, and construct a very rude and simple fabric of a few sticks, which is the general structure of nests among those pigeons which nestle in trees and shrubs.

Parrot Pigeon (V. psittacea). This is a species belonging to the Molucca Islands, measuring ten inches and a half in length, and having all the clothing plumage of a beautiful green. The principal quills are black; the secondaries are the same, margined with yellow; the bill is reddish-grey, and the feet blackish brown. Though there is little variety of colour in the parrot pigeon, it is one of the most beautiful of the whole race; and we may remark, in passing, that many of the pigeons of the Moluccas, in which islands they are very numerous, are remarkable for the greenness of their colours.

The Commander Pigeon (V. militaris), is an Indian species a foot long. The upper parts are pale green; the neck yellow, marked with a band of ash colour; the rump grey, a spot of purple brown on the bastard wing; the quills black, bordered with yellow; the lateral tail-feathers bordered with grey, the under part bluish grey, the thighs yellow, the tail-coverts russet, with blue tips; the bill of a grey colour, and very stout; and the feet red.

Abyssinian Pigeon (V. Abyssinica). This species was first made known to Europeans by Bruce. It is yellowish green on the upper part, bluish green on the head and neck, violet red on the smaller wing-coverts, yellow, bordered with black, on the large. The quills are black, with yellow borders. The tail-feathers are bluish grey on the upper side, and blackish on the under, with grey toward the tips. The under parts are yellow, clouded with orange, and the under tail-coverts are mottled with bluish grey and maroon brown. The bill is yellow at the tip and red at the base, and the feet are orange. The length is eleven inches and a half. The female has the upper part green, the under and also the head olive yellow, the smaller wing-coverts sandy violet, and all the rest of the markings much duller than those of the male.

Purple-crowned Pigeon (V. purpuratus). This is an exceedingly beautiful bird, a native of the Society Islands, and may be taken as a specimen of the pigeons of that part of the world. Its bill, though still hard at the tip, is by no means so powerful, in proportion to the size of the bird, as those which we have previously mentioned, and its general aspect is more light and delicate. Its notes are also more soft, and are said to resemble those of the turtle. The upper part, including the tail, the neck and head as far as over the eyes, and the sides and flanks, are very rich and glossy green. The top of the head is lilac purple, surrounded by a narrow line of rich yellow. The chin and throat are yellowish, and the green toward the head is of a lighter shade than on the body, and glossed with grey. The feathers on the breast have also reflections of grey toward their extremities, and their terminations are peculiar, as the shaft ends abruptly, and the webs on each side project beyond it, as if a triangular piece had been cut out of the feather. The primary quills are black and green, margined with bright yellow. The tail-feathers are also black and green, except the two central ones, which are wholly green, with some markings of yellow; and the lateral tail-feathers have the same form of tips as those which are mentioned on the breast. The tarsi are feathered down to the toes, and the toes are much margined, and furnished with

strong claws. The bird is decidedly a tree bird, living upon fruits, but it is understood that they are fruits of a softer character than those upon which the species formerly mentioned subsist. There are a good many other species, resembling this one in their structure and habits, to be met with in the Molucca and South Sea Islands but as they differ but little from this one except in colour, we need not allude to them.

Magnificent Pigeon (V. magnifica). This one differs in several respects from those tree pigeons of the east, of which we have mentioned one or two specimens. It is much larger, measuring seventeen inches in length; and it has the bill differently formed, though still of the same consistency with those of the others. The membranous enlargement at the base of the bill is exceedingly small; and the bill itself is slender in the flexible part, though compressed and hard toward the tip. The forehead is also lower in proportion, indicating that the muscles which close the bill are not so powerful, and that the work which it has to perform is of a more easy description. In consequence of what has been now stated, this pigeon, and a few others which resemble it in most of the particulars, though one of them has the enlargement on the base of the bill swelled out to a considerable knob, have been called fruit-eating pigeons by way of eminence. They are found in all the eastern islands and in New Holland, and it is probable that they migrate seasonally between New Guinea and the few rich spots which occur on the east coast of New Holland.

The upper parts of the magnificent pigeon are rich golden green, which shows various shades of brown and purple, and even of yellow and red as the light falls differently upon it. The wing-coverts are spotted with yellow, the quills and tail-feathers are of a most intense green, varying in its tints in the same manner as the green on the back. Altogether the upper part of this bird is pre-eminently splendid; the other parts are not much inferior. The head and upper parts of the neck are bluish grey, passing gradually into the green on the lower part of the neck backwards. From the base of the lower mandible or near it there begins with a point, but gradually increasing in breadth, a very beautiful port-coloured streak, which spreads over the breast and all the under part. The basal parts and the feathers in this are deep bluish green, and the margin of each feather is very rich bluish purple. The feathers are broad and rounded at their extremities, and the purple arches which the borders on these form, show off the green in an exceedingly pleasing manner. A small portion at each side on the fore part of the neck has the basal parts of the feathers pale greyish green, and the margins broader and more red. The lower part of the belly, the thighs, and all the under coverts of the wings, are exceedingly rich yellow, with a slight tinge of orange. A skin which the writer of this article got direct from Moreton Bay, in Australia, had a faint dash of yellowish red on the bastard wing; but that is not mentioned in the general description, so that it is probable that this splendid species is, like many others of the family, subject to variations of colour. The basal part of the bill is orange brown, but the hard part toward the tip is yellowish white. The feet are bluish black, with short tarsi thinly clothed with yellow feathers down the front half of their circumference. The toes are stout, and the claws strong and much hooked, but the

external front toe is not so long in proportion as in those formerly described. The foot, though thus a good perching foot, wants the climbing characters which the others have. Altogether this is one of the most gorgeous of the feathered race, whether we regard the intense colour and rich glosses of the upper part, or the beautiful diversification of the under. It should seem that these birds are subject to variations in size as well as in colour, or that there is a species considerably smaller bearing a very great resemblance to this one.

There are a few other species, approaching this one in size, and resembling it in the upper plumage, but greyish green dashed with vinous red on the upper part, and having the bill and feet differently coloured, which have been met with in the isles a good way to the eastward; but as no difference in manners has been observed, and the essential parts of their structures are very much alike, they do not require to be enumerated. Some of these have the membrane at the base of the bill swelled into a knob; but as this is the case in some varieties of the common pigeon and not in others, it cannot be regarded as forming a specific character, or in fact as being anything more than accidental. One species remains, resembling these in some respects, but differing from them in others, which deserves a short notice. This is

The Pheasant Pigeon (V. Phasianella). In the structure of its feet and the form of its bill it does not differ greatly from the species last described, but the tail and the colours of the plumage are very different. Its length is altogether about fifteen inches, of which the tail occupies at least a half, so that it is much shorter in the body than the magnificent pigeon; it is also more slender in proportion, and therefore altogether a much smaller bird. The upper part of it is reddish brown, and the sides and top of the head pretty bright red; on the upper part of the neck especially there are rich reflections of violet purple, varying in different lights. The coverts of the wings are brown bordered with red, and the quills are nearly the same colour only a little darker. The two middle feathers of the tail are entirely brown, and the lateral ones, which are of the same colour for the greater part of their length, are crossed by a bar of brownish black. The throat is yellowish white, and the remainder of the under part yellowish brown, passing first into orange brown and then into reddish brown. The tail is very strong at its base, and well fortified by coverts, but it is much wedge-shaped, or rather has the appearance of the half of a very lengthened oval. The bill is reddish brown, darker in the hard part, and the toes and naked parts of the tarsi are deep orange red. In the shortness of the tarsi, and the general structure of the bird, it very much resembles the magnificent pigeon. The shape of the head is different, however, being more flattened on the top, and meeting the bill less abruptly, which gives the bill the appearance of greater length.

It is found in the very same countries as the magnificent pigeon and those which resemble it in structure. The form of the tail is also the same, only it is much larger in this one. What difference of habit may be connected with this is not known, but the general agreement of the birds is such that in all probability it is not very great.

PIGEONS PROPERLY SO CALLED (*Columba*). This is by far the most numerous genus, and the members

of it differ greatly from each other in appearance. In consequence of these differences it has been divided and sub-divided various ways. There is not much apparent advantage in these divisions; and when we consider the vast number of varieties into which the common pigeon has been broken, and the great differences of form, colour, and habit, which are found among these, we ought not to lay much stress upon the differences which we find in those which inhabit countries of different characters, and consequently live upon different kinds of food.

The most important natural difference in the whole genus, numerous and various as it is, is that between the common pigeon and all the rest. The nesting places of some of the rest are not known, but so far as is known they all build in trees, and the whole of them perch or roost for the night. The common pigeon again, whether in the wild state as the rock-dove, collected in pigeon-houses, or in any of the numerous fancy varieties, never nestles in trees, and never perches in them for the night. Its natural dwelling is in the rocks; and the pigeon-houses, whether on a large scale or on a small one, which it prefers, are those which contain little cavities or boxes, in which the birds can sleep and nestle. So well is this known, that "pigeon-holes" has become the common name of a little collection of vertical openings whatever may be the use to which they are applied.

There is still another distinction which is worthy of being attended to; all the others are wild birds, and cannot be made to return to an artificial habitation if they are once allowed to escape from it. There is no exception to this; and though many of the species seek their food in seeds that are scattered upon the ground, they all betake themselves to the thick shades of trees when they are to repose. They may be often seen on the wing in different kinds of flight, according to the differences of their habits; but they are never found resting on the house tops, or on the rocks, and they maintain their characters. With the others it is very different; for if a convenient pigeon-house is built nearer the feeding-grounds than the rocks which they naturally inhabit, the wild ones will quit the rocks and very speedily fill the pigeon-house. They are therefore birds which seek the vicinity of man, though not his society, while all the rest of the genus belong strictly to wild nature; and when man clears and cultivates to the full breadth of the land, their habitations and their place in nature may be said to be gone. These distinctions apply to the general habits of the birds, and they do not admit of change; so that they are of far more importance than distinctions of shape, colour, and size, which, as we have said, have been artificially produced to a very great extent, in the only case to which artificial means can be applied.

The pigeons properly so called, are not only more numerous in species and in individuals than any of the other two genera of the family, but they are also far more widely distributed. We mentioned that the pasture of the strong-billed pigeons of the east is very extended, but it is really nothing when compared with that of the present genus. The whole land, with the exception perhaps of some remote islands, is their pasture, from near the north polar circle to as far south as habitable land extends; and if we except some of the crow tribe, and the birds of prey, there are perhaps no birds so generally spread over the world as the pigeons. We shall now notice a few of

the species as briefly as possible; and though we ought perhaps to begin with the common pigeon, the dove *par excellence*, which is the type to which the popular mind refers, yet we shall take some of those which are more remote in their localities and less known in their manners. Before we do this, however, there are some general characters of the genus which deserve to be noticed, notwithstanding the extent to which they vary in the species. The bill is of moderate length and strength, flexible in the basal part, and hard at the tip, but not so hard, for so much of its length, or trenchant, as the bills of the former genus. The upper mandible is more or less hooked at the tip, and both mandibles are more or less arched in their outlines. The nostrils are, near the base of the bill, partly covered by a large projecting membrane; and there is a lore or naked space around the eyes. The feet too are walking feet, as well as perching feet, though in different species they take more of one character or of the other, according to the habit. The feet of the common pigeon are for instance walking feet, with very little of the perching character. The external and internal front toes are of equal length, the hind toe is short, and the claws are not hooked, as in the decided perchers, but so placed as that the foot may be wholly planted upon the ground.

There are one or two pigeons included by Cuvier in this section of the genus which do not appear to come very correctly either within it or any of the other two. They are, however, birds of distant lands, and very little is known of their habits. None, we believe, of the true pigeons, of which the rock pigeon may be regarded as the type, are inhabitants exclusively of warm countries, nor are they found, very much resembling the common pigeon, in the south and the east, where the true strong-billed pigeons of great beauty, the nectar-sucking pigeons, and the ground pigeons are so very numerous. The species which most resemble them there, are woodland birds, not ground birds, and, as we said, some of them are but little known, except in their external appearance, and their general agreement with the genus as pigeons and not any other birds.

A further distinction has been made between pigeons and turtles; and the birds to which the last of these names has been given, differ a little from the pigeons properly so called, both in their geographical distribution and in their manners. The turtles, of whatever part of the world they may be natives, and however much they may differ from each other, are inhabitants of warmer climates than the pigeons. Their bills are smaller also, their bodies are more slender, their tails are, in many of the species, more produced; and they are more discursive and inclined to be migratory. In all the species too, to which the name of turtles have been applied, whether correctly or incorrectly it is not for us to decide, there is an exclusive disposition to be woodland in their repose and nesting, though some generally, and many at most times, find their food upon the ground or near it, in the fruits of bushes and the seeds of herbaceous plants. But those distinctions, though of great importance in the estimation of those who are great sticklers for nice differences, are of no value whatever to the general reader, and therefore we shall pass them, and proceed to our selection of this species.

Goura Pigeon. In respect of size, and from the very elegant crest with which the head is ornamented,

this is one of the most splendid birds of the whole family; and there have been a good many puzzles about it as to the place in the system of ornithology it should occupy. It has been called the crested pigeon, the great crowned pigeon, the Indian crested pheasant, the pigeon hocco, the gallinaceous pigeon, and a number of other names, all of which are calculated to mislead the tyro in natural history.

It is a large bird, measuring two feet three inches in the extreme length, and rather stoutly made in the body. The head and neck are not very large, and the bill, though of moderate length, is slender, though fortified with a slight enlargement towards the tip. The tarsi and toes are stout, but the tarsi, though longer than the middle toe, are not very long as compared with those of some of the ground pigeons; and from the general form of the feet, the bird cannot be a very swift walker. The crest is of a peculiar form, consisting of long and beautiful feathers, placed longitudinally on the mesial line of the head, spreading like a fan, and reaching over the bill and the nape, forming a continuous curve at their distal extremities. The bill is about two inches long, black in the basal part, but inclining to greyish-white at the tip. The crest, head, neck, and all the under part of the body, are pale bluish grey, glossed with reflections of blue and purple. The back, the shoulders, and the smaller coverts of the wings, have the basal part of the feathers black, and the terminal parts rich purple with bronze reflections. The greater coverts are black at the base, white in the middle, and purple at the extremities, the white making a very conspicuous bar in the closed wing. The quills and tail-feathers are deep grey, the latter being marked with pale greenish grey at the tip and distal margins. The tail, though not very long, is strong and rounded as in the common rock pigeon; but the wings are not nearly so long in proportion, or so pointed as in that bird.

This splendid bird is a native of the Indian Archipelago, over the wooded parts of which it is very generally distributed. It occurs as far west as Java, if not as Sumatra, and eastward as far as the Molucca Islands, and it is very abundant in New Guinea. It is a wood pigeon, but feeds on the berries and seeds of more lowly plants than the strong-billed pigeons. Its short and rounded wings, and broad and strong tail, show that the habit of its flight must consist in a great measure of ascending and descending; and therefore we naturally conclude that it is not so discursive as the light-bodied pigeons with long and pointed wings. It builds in trees, the eggs being two in a hatch, but how many hatches occur in the course of a year has not been ascertained. During the breeding time the male and female pay the same attention to each other as is done by pigeons generally. The general voice of the male is also that of the pigeons, being a deep but not unpleasant cooing. He also utters occasionally another sound, like that of a slight explosion from the wind-pipe. This is one of the reasons why these birds have sometimes been classed with the hoccoes, but the manners of the birds are totally different; for this, like all the other wood-pigeons, is untameable by any known process, whereas birds of the other genus are, generally speaking, tamed with the greatest ease, and some of them are capable of some training. Besides they are ground birds, and natives of America. This large and splendid pigeon is a valuable as well as a handsome bird, its flesh being highly esteemed, and in considerable

quantity, in consequence of the large size; and the perennial supply of food in the native country. The Dutch, who have been longer and more intimately acquainted with the oriental islands than any other European nation, have paid a good deal of attention to this bird, and they have frequently brought specimens of it to Europe, in the hopes of naturalising it in Holland. Their attempts have, however, always failed, because the bird, being a native of the eastern isles, is not able to bear the rigour of a European climate; and probably, from its habits, it would not thrive, how well soever it might be protected from the cold.

Double-crested Pigeon. In some respects there is a slight resemblance between this species and the former, though in others they differ, and this one makes a nearer approach to the common pigeons. It is a native of the east, and, though specimens for Britain have chiefly been brought from Australia, it has we believe been found in New Guinea, and even as far north as New Holland. Though by no means equal to the former in size, this is still one of the largest of the pigeon family, sometimes extending to a foot and a half in extreme length. The tail is not so strong as in the former; but the wings are much longer and more pointed, indicating a bird of powerful flight. The bill is shorter and stouter than in the last; of an orange colour, and having the tip of the under mandible shorter than that of the upper. The crest consists of thread-like feathers, and, though by no means so handsome as that of the former, yet gives an interesting appearance to the head. There are not so properly two crests as one crest continued along the middle line of the head, from the bill to the hind head, the frontal portion of it being bluish-grey, and the occipital portion reddish-brown. The upper parts are very dark grey, and the under parts bluish ash. The head is ash; the quills and tail-feathers are blackish, crossed by a band of pale reddish grey near the tip; the tarsi and toes are crimson; and the hind toe is very stout. The feathers on the sides and front of the neck are bluish-black at their bases, and pale greyish-ash where exposed. Their terminations are of a peculiar shape; the broad part of the web parts off towards each side in a curving fork, and the shaft is continued in a small feather which has the appearance of being let in between the other two. The habits of this species are not very well known; but it is supposed that they in part resemble those of the goura pigeon, though this bird is much better adapted for flight, and on that account ranges to greater distances.

Chestnut-shouldered Pigeon. This species is larger than the double-crested, measuring about twenty inches in length. It belongs to the Eastern Isles, but has been met with much farther east than the goura or the double-crest. It is a beautiful bird, and all the colours of its plumage on the upper part are finely glossed with reflections of metallic lustre. The bill is yellowish-grey; the head, fore neck, sides of the neck, and breast, are deep green richly glossed; the back of the head and hind neck is reddish-green; the back and scapulars are reddish-brown, with rich reflections; all the under part from the breast is pure white; the wings are greyish, with green reflections; and the middle coverts of the same are rich green. The tail-feathers are brown, with purple reflections for the greater part of their length passing into dark yellow at the tips. This bird has been found in the islands far

to the eastward; and, from its resemblance to the wood pigeons, it is presumed to have habits not very different from theirs, but those habits are not known.

We now proceed to the pigeons of the other parts of the world, of which the habits are better known, and therefore the descriptions of them can be rendered more interesting. In so far as man is connected with them, the rock pigeon, as the parent stock of all those varieties into which pigeons which know their homes, and return to them of their own accord, have been broken by artificial treatment, is undoubtedly the typical bird; in wild nature, however, the case is very different, because the habit which makes this pigeon so manageable by man, and so ready in coming about his dwelling, is peculiar to itself, and, so far as we know, not in the least partaken off by any of the others. It must therefore have been the dove which was sent out of the ark and returned again with the olive branch; for there is none of the rest which would have returned, if it had once escaped from a place of confinement. For these reasons, we think that the rock-pigeon is better entitled to be regarded as a separate section or subgenus than any of the others, because it is distinguished not only by a well-known habit, but by a habit which it never loses, and which may be improved by training, of which the carrier-pigeons afford a very remarkable instance. As any one may observe, there is an elevation of the frontal line, and an air of sagacity in the head of the rock-pigeon, not to be observed in any other member of the family, numerous as they are.

The Ringed Pigeon is the most abundant species in the groves and thickets of the cultivated parts of Britain; and, though it still retains as much of the wild character as to resist every attempt at domestication, it seems to prefer artificial plantings in the midst of rich fields of grain, leguminous plants, and ferns, to those woods which the hand of nature plants in the wilds. Accordingly it is rare in those parts of the country where there is little cultivation; and its numbers increase always as improvement and culture extend. It is one of the most interesting birds of our groves, beautiful in its plumage, and soft and melodious in the tones of its cooing. Every school-boy is acquainted with the note of the *cushat*; and, if we except the cuckoo, there are few birds which have so many human imitators.

It is not a bird of the colder latitudes, and cannot brave the elements in such style as the rock-dove when in the wild state. Its locality is therefore a little farther to the south, though it does not appear to reach nearly to the equator. The central and southern parts of Europe appear to be its headquarters, though the authorities mention it as ranging from Siberia to Madeira. There is little probability of its occurring to the southward of the African desert; and those parts of central Asia and Siberia which are destitute of timber are also unsuited to its habits. Copied broken by open spaces where the trees are thick and shady, but not too lofty, are the places for which it is adapted. Hence it would be vain to look for it in the tangled and lofty forests of tropical countries, or on the wide plains seasonally burned up with drought, with which those forests are interspersed. It has not been found in America, and we should suppose that there would be little use in looking for it there. It is pre-eminently a European bird, stationary in many places, but migratory in a few, yet not to any very great distance. In many parts of

Britain its habits are in so far migratory, and there may be said to be a general movement southward as the winter sets in, and northward as the warm weather begins to return. This, however, is not to be regarded as the principal movement of these birds, their progress being from the colder parts of the same district to the warmer; and if the very early spring is moderately mild, they speedily take their departure for the groves, and commence the labours of the year. As is the case with the whole family, they then disperse in pairs, having congregated into considerable flocks during the winter, and flocks always the more numerous the more completely that the severity of the winter drives them from the woodlands. As is the case with all birds which collect in flocks during the winter, and disperse in pairs during the breeding season, the whole flock does not disappear at once, but gradually melts away, according as the lands are differently affected by the genial influence of the stimulating season. Being early breeders, they prefer copes of firs and evergreen to those of deciduous trees; and the song of the male, if song it can be called, does not begin till there is cover in which he may be concealed. Previous to this, however, he gives a very peculiar demonstration of his energy by evolutions upon the wing, in the course of which he bounds upward and plunges downward with great rapidity, as if to convince his partner how well he is able to bear his part in the maintenance of the family; and when he is to drop down in nearly a perpendicular direction, he dashes the tips of his powerful wings against each other behind his back, with a very audible sound, and down he drops with motionless wing, for a good many yards. The instant, however, that the wings strike downward, the length and power of their stroke give him great buoyancy, and he shoots upward with not a great deal more slope than that on which he descended. This peculiar kind of flight is perceptible with lapwings and other species of energetic birds, in the early part of the season, and when nothing is disturbing or threatening them. Therefore it may be considered as connected with the pairing energy; but whether it tends to stimulate that energy, or to exhaust the excess of it until the nest is formed, it is impossible to say. When the season advances so far, both birds betake themselves to their cover, and the song is begun. This song is very soft and plaintive, though it consists only of four notes at the most. These notes are really in substance the repetition of a single note, but the first and second are long, and the third and fourth short, and the two notes of each time are varied by modulation. Where there is a cover of evergreens, this song begins in February; and, while it is uttering, the songster is rarely seen. Whenever the song begins it may be understood that the construction or repairing of the nest begins also. This is an operation which is short in time, and by no means severe in labour. The nest consists of a few twigs, loosely put together, and so open that, if it can be got sight of, the eggs may be seen by an observer below. This circumstance indeed occasions the loss of very many of the eggs, especially of the first brood of the year. Sometimes they fall down, but more frequently they are observed by boys; and, as the kind of trees which the ring-dove prefers can be climbed to the height of the nest by even a very timid urchin, they are taken without mercy; and thus, though the ring-dove builds in so shadowy places, perhaps more of its eggs are plundered, at

least in copses in the neighbourhood of villages, than of almost any other bird. The eggs are always two in number, of a white colour, rather lengthened in form, with both ends about equally thick. The male does not feed the female while on the nest, but takes his turn with her in the incubation, which is perhaps nearly equally done by the pair. Notwithstanding the open structure of the nest, the warmth of the birds, the limited number of the eggs, and the constant sitting of one or the other of the parent birds upon them, bring forward the incubation in rather less than three weeks. When the young first break the shell, they are in a very callow and immature state, blind, of a dark lead colour, and covered with a thin sprinkling of yellowish down. While they are in this state the parent birds do not feed them with food in its natural state, such as they themselves subsist on. They give them a sort of milky pap from the stomach, which is the food of the parent birds, or rather part of it, reduced to chyme and mixed with the gastric fluids of the parents. It has been said that not only in these but in several other species of pigeons, the craw or first stomach secretes a fluid during the time when the young require this sort of feeding, which it does not secrete at other times, and that there is thus in them a slight resemblance in this respect to the mammalia; but this point, though a curious one, is not very clearly established. It is certain, however, that as the young advance to maturity the nature of their food, which is still delivered from the craw of the old birds, becomes less and less changed from the state in which it was taken by these birds for their own nourishment, so that, by the time that the young are fledged and have strength to shift for themselves, their digestive powers are fitted for that kind of nutriment which their own exertions can find for them. The young are usually fledged by the end of April; and after this there is generally a time of silence and retirement into the depths of the forests, until about the end of July, or the beginning of August, according to the earliness of the season and the plentifulness of food, the labours are renewed, and an autumnal brood is reared. In very favourable places, where of course the spring brood is earlier, there is an intermediate or summer brood, and of course two pauses or times of silence during the season.

The beauty, the size, and even the apparent familiarity of the ring-dove, in preferring the cultivated parts of the country to the wild ones, have led many to wish, and not a few to conclude, that it would be brought into a state of domestication. Accordingly, the eggs have been procured from the nest, and placed under tame pigeons, which have sat upon them and hatched them, and also reared the young with as much tenderness as if they had been their own offspring; but whenever these young attained the proper power of flight, they invariably made off to their place in wild nature, and returned no more. Attempts have also been made, we believe, to obtain hybrids, but they have never succeeded; and there is a line of distinction between the two, especially in their manners, which is sufficient to convince any one that all such attempts are hopeless. As to the domestication again, it is equally hopeless; for, in order that a bird may be readily domesticated, or dwell with man without confinement, that bird must be social the whole year round; and if this sociality is to be judged of from one season, the breeding season is the one upon which the judgment ought to be founded.

The reason of this is quite apparent, from the fact that at that particular season all the energies and propensities of the bird are most completely developed. It is the same with by far the greater number of the mammalia; and indeed it seems to be a very general law of nature.

In autumn, indeed, the ring pigeons do begin to associate in flocks. They do this about the time when the fields are cleared of the grain and leguminous crops, and when beech mast, and various other fruits of the forest trees, begin to be strewn upon the ground. This is seldom later than November in many parts of the country, and in some places it is as early as October. The grains and seeds left, and the small fallen fruits, are their first subsistence; but, as they are ravenous feeders, they, if in great numbers, very speedily exhaust these. After this they migrate lower down, and attack the more succulent green leaves which are left in the fields, such as those of field greens, turnips, and mangold wurtzel, and as they get very fat and vigorous during the time that they are feeding on the grains and small fruits, they are well prepared for enduring the severer and less abundant part of the winter. During these flockings they never nestle upon the ground, but always betake themselves to trees in order to perch for the night; and though at this time they fly with rapidity from pasture to pasture, they make no sound except with their wings. The ring-dove measures about a foot and a half in the stretch of the wings. The weight is not so great in proportion to the dimensions as in some of the other species, but it is more graceful in its form. The colours are very fine, and remarkably uniform in the different individuals, for a species so widely distributed. The head and neck are of a very peculiar grey colour, which reflects green in some lights, and greenish black in others, and it is marked with bars of darker colour on the hind neck. The ring from which the bird gets its name is not a complete collar surrounding the neck, but consists of two patches, one on each side, approaching each other in the front and nearly meeting behind. The under parts are purplish red, with reflections varying from deep purple to clear green. The upper parts are grey, of the same changing colour as the head, but consisting of two different shades which pass gradually into each other. The mantle, or upper part of the back, together with the coverts of the wings, are darkish grey; and the lower part of the back, the rump, and tail-coverts, are pale grey, passing into purple grey on the last. The tail-feathers, which are nearly squared over, or at least very slightly wedged at the extremity and blackish in the middle, are margined with bluish grey, and have faint reflections of purple and greenish brown. The bill is orange, but the cere or naked skin at the base is covered with a mealy powder of a white colour. This bill is of a moderate length, slightly arched at the tip of the upper mandible, and without any margin. The feet are pale red and the claws black. In their form the feet are neither those of the typical tree pigeons or of the typical ground pigeons, but something intermediate between the two; the outer and inner toes are of equal length, and the hind toe is rather stout, but not furnished with so broad a margin as it is in those pigeons which seek their food on trees, it being understood that this one is almost, if not altogether, a ground feeder.

Such are the leading particulars of this, the most interesting perhaps of our copse birds; and we have

only to add, that though there is no hope of the bird being brought into a state of domestication, yet a pair which were confined in the gardens of the Zoological Society of London, produced a couple of eggs in 1834, though the birds were in a state of confinement.

The Wood Pigeon.—This is also known as a British bird, though it is much more rare than the ring pigeon, confined to more peculiar localities, and more confined in its manners. This species still remains to be popularly called the *stock dove*, and the *wood pigeon*, both of which names imply, that when they were given to it it was understood to be the parent stock of the tame pigeons in all their varieties. The names tend to keep up a belief in the mistake, and therefore the sooner they cease to be used the better. In some of its habits it bears a considerable resemblance to the ring pigeons, but it differs considerably in others, and also in its habits, its size, and its form. It is by no means so handsome a bird, and it is inferior in size, being only about fourteen inches in length, and twenty-six in the stretch of its wings. It is, however, better winged for its length than the ring pigeon, and its habits correspond. In Britain it is, as we have said, rare, and almost confined to the midland counties, whereas the ring pigeon is found in almost all the cultivated parts where there are plantations, and the rock pigeon reaches the extreme north. On the continent of Europe it is much more common and also much more discursive than it is with us. In winter it seeks the middle and southern latitudes, but in summer it is distributed much farther to the northward than even the ring pigeon. Its manner of nesting is very similar to that of the former species, and the eggs are the same in number, colour, and shape, but smaller. The broods are also two in the year, one before and the other following the midsummer rest. Flocks accumulate in the autumn, in the same manner as the ring doves do; and the food of the two species is, at these times, precisely the same. Indeed the two often mingle together in the same flock, and seek their food on the same pastures. The wood pigeon is just as incapable of domestication as the ring pigeon; but though it is a woodland breed, it is said to be more constant to its breeding place than the ring pigeon, the pair resorting to the same one for a number of years. We must not suppose that this is inconsistent with the more discursive habit of the bird; for birds which never by any chance migrate, or range above a mile or two, are known to change their breeding places every year; whereas the same pair of house martens, which in all probability go to the distance of many miles in the winter, return every summer, from year to year, to the same corner of the same window.

In very many of its characters the wood pigeon appears to hold an intermediate place between the ring pigeon and the rock pigeon, as we have said it knows its resting place better than the ring dove does, but in this respect it is vastly inferior to the rock. It also occasionally builds in the hollows of old trees, which the ring pigeon never does, but it is not known ever to build in the cleft of a rock. Its note has not the soft expression of that of the ring dove, neither is it heard at so great a distance. It utters no sound but a low and harsh grunt, and the fact of there being no temptation for the ear in its voice may be one reason why it is so seldom discovered, and this again may cause its numbers to be rated much below what

they are in reality. As food, too, it is superior to the ring dove, but inferior to the common pigeon. As this bird and its eggs are rather more difficult to procure than those of the ring dove, we are not aware that any attempt has been made to procure a mixed breed between them; but the habits of the birds differ so much that there is no question of the failure of the experiment, even if it should be tried. The bill of this bird is rather longer in proportion than that of the former, and the upper mandible is tumid in the middle and curved at the point. The upper parts are dull bluish ash, the head dull bluish grey, and the back and sides of the neck green, with reflections of purple and bronze red. The rump, the wing-coverts, and also the belly, are bright grey. The primary quills are black with white margins, and the middle ones are ash-coloured tipped with black, forming two spots of that colour on the wing. The tail-feathers are black ash-coloured at the base, and marked on the under side by a band of grey. The lower neck and breast are vinous red, the bill orange red, the feet dull red, and the claws black.

The Rock Pigeon. Though, as we have hinted, this species ought to stand distinct from all the tree pigeons and perching pigeons, yet, as it resembles in shape and in some of its characters, at least when in the wild state, the ring and wood pigeons much more than it resembles any other, we shall introduce our short notice of it here; and as the numerous artificial varieties belong to bird-fancying rather than to natural history, we shall chiefly confine ourselves to the bird as in a state of wild nature, and as a sort of voluntary dweller in artificial pigeon-houses. If we have occasion to say anything more than this, it will only be to point out the curious deviations from the simple form in the natural state, which artificial treatment has produced in this species of bird. Even in pigeon-houses, where almost the only thing which art does for them, is to provide them with an artificial dwelling more comfortable than those in which they naturally take up their residence, and situated in the closer vicinity of rich pastures for their feeding, even there they are very prone to break into varieties of colour, and in proportion as they are brought nearer and nearer to the house, they deviate farther and farther from the appearance of the bird in a state of nature; and some of them become so fantastic in appearance, as to differ more from the parent stock than other species with which that stock is little if anything allied. Amid all these varieties, however, there are certain characters of the wild bird which are never entirely obliterated. There are two dusky bars across each of the closed wings, and some white in the rump. If the general colour is white, the superior whiteness on the rump is of course not easily discerned; but even then the bars on the wings may be traced. In the state of nature, the appearance of these birds may be briefly described in the following terms: the body very compact, the shoulders tapering finely to the neck, the top of the head flat, the front elevated, and the bill of moderate length; the tail long and more rounded at the extremity than in either of the other British species, and the wings long and pointed; the head and throat are bluish-grey, and so are the lower part of the breast and the belly; the upper part of the breast and sides of the neck are brownish-purple, with reflections of purplish red and green; the mantle and smaller coverts of the wings are bluish-grey; the lower part of the back,

is white, passing into bluish-grey on the tail-coverts, and into deeper grey on the tail-feathers, which are crossed by a dusky band near the tips; the greater coverts and the secondary quills are crossed with black, and form the bars already alluded to, when the wings are closed; the principal quills are blackish; the bill and feet are reddish; the length is about thirteen inches, and the stretch of the wings not much less than two feet; the plumage over the whole body, both in the clothing feathers and in the feathers of flight, is remarkably close and compact, and the birds have great power of themselves in the air, even when the wind blows with considerable violence.

They would require this preparation at the hand of nature in consequence of the severe storms which they often experience at those places where they reside and nestle. It does not appear that there is, generally speaking, much food for them in the close vicinity of these their natural habitations. But in order to keep up the powerful and long-continued muscular action which they must exert, they require a high degree of action in the vital system, and, consequently, a copious and frequent supply of food. In order to obtain this they must range about in all weathers, and consequently they require to have great management of themselves in the air. On their long flights in a state of nature they are not very often seen; but after they have taken up their abode in pigeon-houses, their flight is lower; yet even the ones which live in small numbers about houses, and are fed without much effort on their part, may often be seen wheeling and driving very gracefully through the air, apparently for no other purpose than that of exercising their wings.

It is highly probable that the labour which they feel in returning from long distances when they are heavy with feeding, is one of their great inducements to take up their abodes in artificial pigeon-houses. The general belief, and we have no reason to doubt the truth of it, is that they are attracted by whitened pigeon-houses, much more than by those which are of a dark colour. There may be two reasons for this; first the whitened pigeon-house is a more conspicuous object than the other; and, secondly, a considerable quantity of carbonate of lime *may* be required for the eggs of the females, which, though only two in each hatch, are often numerous in the course of the year. Even under the most unfavourable circumstances, there are seldom fewer than three hatches in they ear, and sometimes there are as many as a dozen. The latter of course takes place only in rich pastures; but still the birds are highly prolific.

In those lofty cliffs overhanging the sea, which are the favourite resorts of rock pigeons, caves are the places in which they repose and nestle, and rear their broods; and the darker the cave is, it is understood to be the more favourable for them. Such caverns are chosen as nesting places by many sea-birds which find their food on the waters; but though the rock pigeon takes nothing from the water, it inhabits farther into the cave than the most habitual diver, or the bird most discursive over and dependent upon the sea. It is true that these birds are often found on the beaches walking about and picking up something; but whether they pick up any part of their food there, or merely bits of shells and small pebbles, it is not easy to say.

Upon the rocky parts of the west of Scotland, and the bold shores of the western isles, some of which are

rocky and caverned enough, these birds abound perhaps more than in any other parts of the British islands. As the shores of the main land are exposed to the winds of the Atlantic, and the comparatively small islands are surrounded by that ocean, the low grounds exposed to the west are seldom covered with snow for any length of time, and thus the birds easily find a supply of food. The numbers which congregate on one shore, and even in one cave, if it be large and lofty enough, are often very great; and the boatmen who convey strangers to visit the caves into which the tide enters for a considerable distance, very generally take advantage of the pigeons, as a means of giving their fare a surprise, which is rather startling to those to whom it is entirely new. They row into the cave as silently as possible until they have advanced some little way. Then the steersman seizes a fowling piece which has been stowed away, and the rowers cease pulling. In an instant, and before the passengers have time to inquire what is the matter, the musket is discharged; the rowers thunder on the gunwale with their oars, and out dash the pigeons in a torrent flood, making so loud a rustling and rumbling with their wings, that those to whom it is a novelty, can hardly persuade themselves that the whole materials of the cave are not hurling down, in order to entomb them in a majestic sepulchre. But the din, though loud and not unalarming, does not last long, as the pigeons are fully as much affrighted as the passengers; and as far as the roof of the cavern can be seen, it is as stable as ever, and not an ounce of stone is loosened from its place. Fingal's cave, in the wild and beautifully green Isle of Staffa, which is perforated through and through under the low-water mark, and absolutely rocks, like an unstable thing, before the swell of the Atlantic, when the majesty of that ocean is up, used to be, if it is not still, a favourite place for this kind of exhibition. The cave is large and lofty, and if the interior of it is not absolutely dark, it is dim twilight; and as much of the roof consists of portions of basaltic columns hanging as it were by simple contact with each other, there are few roofs of caverns, the fall of which would be more likely to be expected by one who does not understand the firm texture and stable union of this wonderful architecture of nature. Another thing, basalt is perhaps the most sonorous of all rocks, and therefore the echoes of the cave itself go to swell the sound made by the numerous wings of its inhabitants.

When the birds are thus disturbed, it is generally in the time of their repose; and hence, after they have escaped from the cave, they fly no farther than they may apprehend that the danger is to follow them. They do not, however, return immediately, but rise to a considerable height in the air, and keep wheeling about as if to show how vain it would be to follow them in that element. Although, however, they are by this means quite safe from the alarm below, and would of course have been so though they had remained in the cave, there is sometimes an enemy above them far more dangerous, at least to one or two, than that which has caused them so much alarm. If one of the large and powerful falcons of the north happens to be above the pigeons in the sky, down he comes with the rush of a thunderbolt, and, striking right and left, tumbles two or three of them down, and then alights to eat them at his leisure.

The love of home, and certainty of return to it, which, in this species, secures the flock to the pigeon-house, and the more wonderful return of the carrier pigeon, even when it has been carried away from home in a basket or hooded, is very conspicuous in the wild rock pigeons, or *bisets*, as they are called by the French. Flocks from different parts of the coast often meet on the feeding grounds; but when the time of returning to rest comes round, each one keeps to its own party.

It is in vain for man to attempt any solution of this upon the principles of human philosophy, any more than it is possible upon the principles of such philosophy, why this pigeon should possess it, and the greater number, if not all the rest, should be without, or than it is possible to explain why a pigeon is a pigeon and not any other bird. But still, though we can arrive at no conclusion upon this subject by reasoning, it is one which is both open and inviting to our observation; and it is perhaps more so in the case of this species of pigeon than it is in any other animal. That the animal does not return in consequence of any remembrance of the way similar to what we call remembrance, is quite evident; because, as we have mentioned, the carrier pigeons are usually brought from their homes, shut up in baskets, or muffled in hoods, so that they can see nothing even on the ground. Besides this, they take the air on their flight at so lofty an elevation, as that they can see nothing upon the ground; and the proof that they would avail themselves of nothing of the kind if they did see it, is perfectly clear from their passing as readily and as certainly over hundreds of miles of sea where there are no marks as over a few miles of land. The instinct, for we have no other name for it, which enables them to do this, appears to be substantially the same in all; for the migratory birds, unless when the strength of the wind happens to drive them from their courses, arrive at their breeding places with the same certainty as the pigeon arrives at its home.

There is, however, a difference in the mode in which the instinct operates; and this difference is the important part of the matter, because it is that which shows that the bird or other animal will come to an artificial habitation to which it is accustomed, whether that habitation be native to it or not. It is true that we can no more explain the reason of this, than we can explain the reason of the general instinct, and it is impossible that we could, inasmuch as there is no reason in the matter; but we do know that whatever bird or other animal can range to a great distance, and return to an artificial home, is always capable of being domesticated to some extent or other. There are few, if any, which have it, and are not serviceable to man in some way or other; and all that have it strongly, are social when in the natural state.

Domestic pigeons, which are nothing but the rock pigeon in a state of greater or less domestication, are kept, that is, encouraged, in pigeon-houses in most parts of the civilised world. We have already expressed doubts as to the profit of having numerous pigeon-houses in districts which are entirely cultivated, and we still lean to the opinion, but would not be so dogmatical upon it as to advise any one to demolish a pigeon-house. Except where there are extensive market gardens, and constant culture, the pigeons must find their own food for the greater part

of the year; and it may be said to be only for two or three months from the first ripening of the early crops to the last gathering in of the late ones, and while the seeds are sowing, or nearly sown in the spring, that they can be said to be very destructive. While the ground is clear and there are no crops to destroy, and this is the time when they are in the best condition for the table, they are really serviceable to the farmer. It is not possible to remove crops, whether cereal or leguminous, from the fields, without leaving a pretty large fraction of the seeds upon the ground. These seeds are not only not wanted there, but if not picked up by pigeons or some other seed-eating birds, they would be a nuisance to a farmer who farmed in a proper manner. If the kind of grain is not changed every year, the farming is bad; and if the seeds which strew the ground, and which often amount to a sowing were allowed to remain, they would grow up, and not only render the future crop foul with the mixture, but diminish its quantity. Examples of this are to be met with in cold and upland places where the crops are long in ripening and the birds are driven away by the cold before the fields are cleared. In such countries one seldom finds a patch of oats without an admixture of barley in it, or a patch of barley without an admixture of oats. Nor is this the worst, for there is a want of little birds upon the fields to pick the seeds of those noxious plants, by which the crops are greatly diminished and their quality injured, and sometimes rendered unwholesome. The people of the midland and southern counties of England, and of rich and warm districts in other parts of the country, may thank the flocking birds of winter that their meadows are so exclusively covered with grass, and their crops so free from weeds—the more so, that in some of the places alluded to, the agriculture is very slovenly, so that, but for the birds, weeds would in a very short time be the staple crop.

It is upon this principle that the utility of pigeon-houses admits of defence; and then the extreme fertility of the birds, the goodness of the flesh of the young ones, and the great value of the clearance of the pigeon-house as a warm and stimulating manure, plead powerfully to the same effect. In districts where pigeons are numerous they also come in in the best condition when the people of the districts have comparatively little time to go in quest of other food, from the necessity of attending to the gathering in of their crops, at the time when the weather begins to break in prelude to the autumnal rains, by which, if the crops are overtaken, the result is always very disastrous. For these reasons we suppose that, after all, we must give our advice in favour of the pigeon-house, though it would be foreign to our purpose to describe minutely the construction and management of a pigeon-house. The house should be on a slope facing the south, and the roof should be a pretty steep southern slope, to enable the birds to bask in the sun. Water should be near, and it should not be shaded, or closely surrounded by trees; it is better, indeed, to stand by itself, so that the birds may not be disturbed in their labours. Though most of the old pigeon-houses are square, a circle is preferable; and it might be defended both inside and out by a projecting ledge below all the pigeon-holes, to prevent destructive animals from reaching there; and, besides this protecting ledge, there should be others higher up for the birds to alight upon as they enter

their abode. Cleansing the inside frequently, and whitewashing the outside as occasion requires, are also very necessary operations. The fact is, that pigeon-houses are like all other things, if they are expected to be profitable they must be attended to; and there are many known instances in which the slovenly keeper of a pigeon-house has found the greater part of his flock go over to the establishment of his neighbour merely because it was in better order, and the reproving deserters made no hesitation in coming to levy their contributions upon the crops of their slovenly master. We have, however, said enough of the wild and the domesticated economy of these birds when allowed to remain in numerous flocks.

Of the fancy varieties we shall do little more than barely mention the names; because there is no certain information upon the only point which, in a natural-history view of the matter, is of any importance, namely, the particular means by which the variations were produced and have been continued. The last part of this is a curious fact. We do know, not from pigeons only, but from many other animals, both birds and mammalia, which break into varieties under the hand of man, that, when the variety is once obtained, it can be continued; and the most curious part of the matter is, that the artificial change may be directed to the size and modified form of the animal, or to the farther development of any of its particular actions or instincts. Thus, in the dog, there is not the slightest doubt that there is only a single natural species of the animal; and yet the sizes, the powers of motion, the disposition, and the senses, are varied to an extent which one can hardly imagine; and yet, excepting in some crosses which have been obtained in times comparatively modern, nothing is known of the matter with anything like certainty. It is the same with the different breeds of fancy pigeons; and yet there could have been no cross in the first splitting into two breeds in either of these or in any other.

The principal breeds or varieties of fancy pigeons (and the distinction between a breed and a variety is really a distinction without a difference) may be briefly enumerated as follows, though to enumerate the whole would be a hopeless task, as they may be increased without end:—the Roman, which is of very varied colours, and has the naked skin at the base of the upper mandible nearly white;—the Norway, which has the body pure white, the feet feathered, and a crest on the head;—the Barbary, which has a naked tuberculated space round the eye, and two dusky spots on each wing;—the Persian, which has the naked skin at the base of the bill red and tuberculated;—the Broach-tailed Shaker, which has a vast number of feathers in the tail, often more than three dozen, with the power of erecting and spreading them like the tail of a turkey-cock; and when it does this, it shakes with violent agitation;—the Narrow-tailed Shaker, a cross with the female of the last, retains the trembling action, but has the tail narrower, consisting of fewer feathers, and incapable of the same spread and erection;—the Jacobin, which has the feathers of the hind head and sides of the neck thread-shaped and erected;—the Laced, which has small standing-up feathers scattered over the back and wings;—the Smiter, which turns over when it flies, and strikes its wings against each other with considerable violence;—the Turner, which has the

feathers on the middle of the hind neck reversed, and standing up like a mane;—the Panter, which has the power of inflating the craw, till it projects forward as far as the point of the bill;—the Houseman, which has also the power of inflating the craw, and the naked skin at the base of the bill warty;—the Turbit, with the feathers on the breast reversed;—the Tumbler, which, while it flies, performs the operation after which it is named much in the same way as the Smiter, but which does not, like that, make a noise by striking the wings against each other;—the Rough-footed, with hair-like feathers on the feet, but without any crest of produced feathers on the head;—the Crested, which has the feet feathered in the same manner as the preceding, and has, in addition, a crest upon the head. These are but a specimen out of many; and as they have no peculiarity of habit answering to their peculiarity of form, or no useful property answering to their peculiarity of action, they are worthy of attention by the bird-fanciers only. There is, however, one other variety which has, from very remote times, engaged so much celebrity, that we cannot pass it over without some slight notice. This species is—

The Carrier Pigeon, or the Messenger. In consequence of its celebrity, and also of the differences between it and the wild rock and pigeon-house pigeon, there have been many disputes about it. Some have maintained that it is a distinct species, but for this there appears to be no good foundation. Many of the other fancy breeds differ as much from the wild bird as it does. It possesses the love of home in a very high degree; and there is no known species in wild nature at all answering to it. Besides, carrier pigeons differ from each other; they vary in size, and the small ones resemble the common pigeon in more points than the large ones do.

The carrier is a larger bird than most varieties of the common pigeon. It is about fifteen inches in length, and a pound and a quarter in weight. The shape of its body is graceful. Its neck is long, and its pectoral muscles are very large, indicating a power of vigorous as well as long-continued flight. Its plumage is remarkably compact, but no general description of the colour of that plumage can be given, as the bird is subject to much variety in this respect. This, of itself, is sufficient to prove the fact that the bird is a mere variety. Black, and a sort of dim sand-colour, are most common; but the blue and pie-bald blue are more rare, and therefore more prized by the curious in birds. The naked skin upon the bill of the carrier pigeon is very large, of a whitish colour, and scurfy or warty appearance, and hanging down as a sort of wattle on each side of the lower mandible. This appendage extends forward, and terminates in a point about the middle of the length of the bill. The cere on the Turkish or Persian pigeon is also large, and scurfy or warty, as in this one; and this circumstance has led some to mistake it for the carrier pigeon. It is, however, a bird of very different habits, low and heavy in its flight, and possessing no particular attachment to its home, not more at least than is possessed by the wild rock or the common pigeon-house pigeon. The fleshy appendage to the bill of the Turkish pigeon is different in appearance from that of the carrier; it extends into a wider naked space round the eye, and it is blotched or mottled with reddish. The colours of the bird are in general different; but, as we have

said, there is no such thing as describing the positive colour of any of the artificial varieties of the pigeon, though in each variety, as forming the breed of a particular place, there is usually one colour which is more prevalent than any other.

The amateurs of carrier pigeons estimate their goodness by the wattle. According to them, it should be broad across the bill, rise high at the head, and have the portion round the eyes as broad as possible. The second of these forms is supposed to be the most valuable; and therefore the dealers sometimes contrive to insinuate a piece of cork below the hind part, and fasten it with a bit of wire, which is of course very injurious to the bird.

As the carrier is unquestionably a species, it is useless to speak about the country in which it is found in the wild state; for, though the country in which these varieties were originally obtained may properly enough be considered as their native country, yet not one of them is to be found continuing its variety in the wild state.

The carrier pigeon has been known and celebrated from the most remote antiquity, and its use as a messenger is repeatedly celebrated by the poets of Arabia, Greece, and Rome. Nor is it confined to them, for the historians make frequent allusions to it as in some instances carrying intelligence with wonderful rapidity, and in others in performing the same office where hostile armies, or other impediments, prevented communication along the ground. *Ælian* mentions that, when *Tanrosthens* was victor at the Olympic games, a carrier pigeon bore the tidings to his father with wonderful celerity. As a contrast to this use of the carrier among the ancient Greeks, it may be mentioned that, at no very remote period, carrier pigeons were employed in England to convey intelligence of the result of games of a very different kind. In the times alluded to, Tyburn was the place of execution for the British metropolis; and, in consequence of the wretched state of the police in town, and the total absence of anything like police in the country, Tyburn was kept pretty constantly at work. It not unfrequently happened, too, that, though the punishment of death was awarded, it was not really intended to inflict more than the disgrace of being drawn on the hurdle from Newgate to Tyburn, or perhaps, in addition to this, a longer or shorter imprisonment. Hence pardons and respites were very frequently given at the foot of the gibbet; and the relations of the criminals, who, in the days of daring highwaymen, were often persons in comparatively elevated situations, naturally felt great anxiety for the fate of the condemned. Hence they used to have some one there with a carrier pigeon, and the instant the result was known, that pigeon was let off, and winged its way at the rate of twenty or thirty miles an hour.

Pliny mentions the use of carrier pigeons to beleaguere cities. When *Modena* was invested, he says—"Of what avail were centinels, circumvallations, or nets obstructing the river, when intelligence could be conveyed by aerial messengers?" In the time of the *Crusades* these pigeons were extensively employed by the people of the invested cities; and there are instances mentioned in which the pigeon was captured by the besiegers, and made the bearer of a very different message from that with which it was originally charged. In some instances hawks were kept by the besieging parties for the express purpose of

being flown at the pigeons; and, as the noble hawk do not strike on the ground, the pigeon dropped like a stone uninjured, and allowed itself to be captured; and the hawk being recalled to the lure, the pigeon was charged with false intelligence, and sent to its original destination.

But these extraordinary birds have been used for the purposes of commerce as well as for those of war; and, when the Turkey Company of England was flourishing, and a number of English merchants were resident at Aleppo, the grand emporium of the trade, carrier pigeons were employed to bring intelligence from the port to the city. Scanderoon, the port of Aleppo, is distant about eighty miles as the pigeon flies. The pigeon could bring intelligence over this distance in not much more than three hours, while it could not come by any other channel in much less than the same number of days. Thus, those merchants who employed pigeons could, upon the arrival of ships, obtain information which they had abundant time to turn to advantage. One case is mentioned, upon authority which there is no reason to doubt, where a merchant killed one of these pigeons by accident, and learned from the billet which it bore that there was a great scarcity of galls in England. Taking advantage of this, and buying up nearly the whole quantity in the market, he at once cleared a sum which, in those days, was considered an ample fortune.

In the east, intelligence was, in former times, communicated by these pigeons much in the same manner as is now done by telegraphs. Slight towers were built along the line, at thirty or forty miles distant from each other, and pigeons were employed in flying from tower to tower. These pigeons wore a very small box of gold, of extreme thinness, suspended from the neck; and, as the pigeon wore this box always, it could carry the message and bring back the intelligence. Centinels were kept constantly watching on the towers; and, as each flew from its own tower to the next and back again, the information, though not so expeditious, certainly could be rendered much more effective than that which the telegraph affords. In England, and we believe we may say in Western Europe generally, in modern times, pigeons have been little, if at all, used for what may be called useful purposes; but they are often employed as matters of curiosity, and as conveying the results of questions upon which bets continue to be taken until they are decided.

Our limits will not, however, allow us to enter farther into the history of these highly interesting birds. We may mention, however, that though there is much in the breed of the pigeon, yet each individual bird must be trained before it can perform its office rightly. Turkey may be considered as the country where these pigeons are more especially employed, and the mode of training them in Turkey is this:—the bird is first taken out in a basket, or hooded, to the distance of about half a mile, and then let go; if it did not return directly from this distance, it was considered as of no value; if it did return directly and swiftly, it was taken to greater and greater distances, until at last it could manage thirty or forty miles with certainty. Those to which we have alluded, as being used by the merchants of Aleppo, were trained all the way to Scanderoon; and if they came directly back, they were counted birds of great value, and brought a high price. As in the case of carrying

intelligence, of which advantage, either military or mercantile, is to be taken, it is of the utmost consequence that the pigeon should not alight upon the ground, means were taken to prevent this. The most urgent necessity which the bird had to descend was in quest of water; and it was found that if its feet were well bathed in vinegar before it started, its tendency to alight was prevented. We have felt it necessary to go a little into the details both of the character and history of the carrier-pigeon; first, because they are very curious; secondly, because they are but little known to ordinary readers; and thirdly, because, rightly studied, they afford much light upon the training of animals so as to make them useful to man. We believe that this kind of training (we allude to the training of carriers) is not confined to this variety of the rock-pigeon, but might be applied to any variety if proper care were bestowed. It is not even confined to pigeons, but seems to be applicable to any bird which habitually lives in a social manner at the same place, and mention is made that the rook has been employed as a carrier in some of the eastern countries, but not frequently we believe.

There are many pigeons bearing some resemblance to those which we have noticed, beginning with the ring-pigeon and ending with the carrier; but, as we have rather exceeded our limits in what we have already said, and as there is very little to be said on the others, except of the differences of size and colour, we shall pass to the remaining subdivision of this branch of the family, namely, those birds to which the appellation *Turtles* is given. They vary much in their forms, appearances, and sizes; the species of them are exceedingly numerous; and they are distributed over every quarter of the world, with the exception of the colder latitudes. They agree, however, in certain general characters: their bills are more slender than those of the typical pigeons; they are in general smaller and more lightly made, altogether more delicate-looking birds, and their tails are less even at the extremity. In all they are longer than the tails of the pigeons, and in many they are very long and wedge-shaped. This is not the case with what may be called the typical turtle, namely, the one species, or rather the two species, which have been known and celebrated from the remotest antiquity. They have the tails rounded at the extremity, and are clad in far more simple attire than the long-tailed ones, which resemble, in the brightness of their plumage, the length of their tails, and partly also in their habits, some of the more slender-billed of the tree pigeons, and on account of this resemblance these tree pigeons have sometimes been called *Turtellines*; but neither these nor the long-tailed turtles are entitled to any share of the poetic fame with which the typical turtles have been invested. Many of the eastern writers celebrated the gentleness of the turtle; and it is long since it was the rival of the nightingale, with allusion to the attachment of the pair. The celebrity of the turtle is not confined to profane writers; for it is enumerated in the catalogue of the beauties or attractions of the sweet season of the year, in that glowing enumeration of them which is given in the second chapter of the Song of Solomon:—"Rise up, my love, my fair one, and come away." The coming was forth into the fields, to enjoy the beauties of nature, and the inducements are as follows:—"For, lo, the winter is past, the rain is over and gone; the flowers appear on the earth:

the time of the singing of birds is come, and the voice of the turtle is heard in our land. The fig tree putteth forth her green figs, and the vines with the tender grape give a good smell. Arise, my love, my fair one, and come away." We have quoted the entire passage, as well for its beauty as from its tending to illustrate a point in the natural history of the turtles, namely, that the turtle alluded to in it is not the common turtle of the warmer parts of Europe, which comes as a summer visitant to a small portion of the south of England, but another turtle whose native locality is still further to the south. Having done so, we may remark, in passing, "that the words of birds," "with," and "good," are not in the original, but have been interpolated by the translators, and, few though they are, they mangle sadly the beauty and power of the passage. The "time of singing" applies to the song of all nature, and the addition of the words "of birds" ties it down to a single class. In like manner the interpolation of the word "with" spoils the beautiful reduplication, the two expressions for the one subject, "the vine—the tender grape." Nor is the word "good" less objectionable, for if it mean anything as applied to a smell it means fragrance, whereas a vine with tender—that is with young grapes, has no fragrance, though it has the freshness of a healthy plant in a state of vigorous growth. But we must notice a few, and it shall be only a few, of the species.

Common Turtle.—Considered as a British bird the common turtle is the smallest and the most local of all our pigeons. The male bird is but twelve inches long, and the female is still smaller. The upper parts are brown; the top of the head and the hind neck ashen grey, each side of the neck garnished with a flat patch of small black feathers with white tips; coverts of the wings brown bordered with russet; quills blackish with whitish borders; tail-feathers brown with white tips to the lateral ones; throat, neck, and breast tinged with vinous red; rest of the under part white. The male generally has a white patch on the forehead, which is wanting on the female; and all the colours of the female are duller than those of the male. The naked skin round the eye is red, the bill bluish, and the feet red. Turtles are, however, subject to considerable diversity of colour, which is understood to depend upon age, upon season, and upon original differences in the individual.

The common turtle is found in Europe, in Asia, and in some parts of Africa, and it ranges much farther to the north on the continent than it does in Britain, though it never extends its summer journey within the arctic circle. It is a delicate as well as a gentle bird, and retires, not only from northern and middle Europe, but even from Greece and Italy, if the winter is severe. As a British bird it comes late in the spring, or rather just about the beginning of summer, never before the end of April, and sometimes not till the middle of May. They occur in pairs, and soon betake themselves to the thick groves, in the closest shadow of which they construct their rude nest, deposit their two eggs, and perform their incubation. During this time their plaintive and tender cooing may often be heard in the neighbourhood of those thickets where they nestle; but the birds themselves are very seldom seen, as in wild nature they are exceedingly shy and retired. They are, however, mild and gentle creatures, and though they cannot be

domesticated, they very soon become tame in confinement. If the pair is caught, their attachment for each other continues, they caress the hand which feeds them, and their whole manners are beautifully simple, and their attitudes remarkably graceful. As we have mentioned of some of the other species, it has been well ascertained, that immediately before the young break the shell the inner coat of the craw becomes glandulous, and secretes a fluid, by means of which the young are fed when in their unfledged and helpless state. When the leguminous plants begin to have seeds in their pods the turtles come more abroad, and it is understood that by this time the young accompany them. They feed upon the ground, or reposing upon herbaceous plants, just as pigeons do; but they roost in the thick cover of the groves, both in their mid-day *siestas* and during the night. In England they have no time to rear a second brood, for in August they begin to appear in little flocks upon Romney Marsh, and other open places near the south-eastern shore, and about the latter end of August they take their departure. Kent is their grand headquarters with us; and small and gentle as they are, they sometimes commit pretty extensive ravages upon the fields of peas. The number of the broods in warmer climates has not been ascertained.

The Collared Turtle.—This is a smaller and more delicate species than the former, and it dwells nearer the land of the sun. It is pretty well ascertained that this species is the turtle alluded to in the Bible, and also the bird which was considered by the mythologists of old as sacred to the goddess of Love. The delicacy of its habits will be readily understood from its being represented in the passage which we have quoted, as a migrant bird, appearing only at the commencement of summer, even in Syria. It has been a great favourite from the earliest recorded times, and it has been in so far domesticated. It is true that it requires to be kept in confinement, but still it will breed in captivity, and it is very prolific if proper attention is bestowed upon it. But though the descendants of the domesticated ones have been continued for many generations, the tendency to escape has never been overcome; so that though it is sometimes called the domestic turtle in distinction from the other, it is really not a domesticated bird, but one which no continuance of breeding in confinement has the least tendency to domesticate. It has not the habit in wild nature upon which domestication depends; and experience has satisfactorily proved, that if an animal has not this habit it cannot be domesticated, however gentle it may be in a state of confinement. The climate of Britain is unfavourable to the breeding of so delicate a bird, without more attention than most people have either time or inclination to bestow upon it; but in warmer climates, where the task is easier, and the labour of man is of less value, it is very extensively kept as an ornamental house bird.

In its habits it is fully as migratory as the common turtle, ranging occasionally through the whole of Africa, and being met with as far south as the Cape. It comes into Europe during the summer, but only into the warmer countries, and there is no instance of its being found in any part of Britain even as an occasional straggler. The length of the bird is rather more than ten inches, its form is light and delicate, its wings long, its tail long and rather rounded, and it is altogether well organised for flight. The colours,

as in the former species, are subject to variation, but the following may be regarded as the average. The clothing feathers on the upper part grey, glossed with a rosy tinge. The coverts of the wings cream yellow, and the tail-feathers ash colour, having white tips to all except the two middle ones, and white margins to the two exterior. The head is bluish grey, darker on the forehead and paler on the front; the cheeks, neck, breast, and belly, are grey, with a purplish shade; there is a half collar of black on the hind neck, terminating in points forwards; and the vent-feathers and under tail-coverts are white. In some specimens, however, the whole plumage is white, with a simple indication of the collar, and the coloured ones are of a great variety of shades. Though this turtle has been celebrated, and justly celebrated, for the gentleness of its manners, and the tenderness of its attachments, it is the common turtle which is the bird of plaintive song; and the voice of this one has more the character of a merry than of a mournful sound, for it has been compared to a short and subdued laugh; and this harmonises with its voice being enumerated among the joyous signs of the coming summer in that passage of the Song of Solomon which we have quoted on a preceding page. This difference of voice, independently altogether of size, colour, and locality, would be sufficient to establish a specific difference between the two; but the point has been further demonstrated by the mixed progeny being capable of self-continuation.

Carolina Turtle. This of course is a North American bird, ranging in the summer as far as Canada, but moving southward in the winter, partially even from the middle states of the American Union. Their great winter quarter appears to be in the Carolinas and states to the south, where they appear in great numbers. They are interesting birds on three accounts: first, on account of the melancholy and affecting sound of their notes during the breeding season; secondly, on account of the high estimation in which the flesh is held, and the ease with which it can be procured in consequence of the familiarity of their manners; and, thirdly, because, in form, they hold a sort of intermediate station between the turtles with the tails rounded, such as the two species which we have noticed, and those with the tails very long and exceedingly wedge-shaped. There is a farther advantage—Alexander Wilson is the historian of their manners.

The following is his description of the birds:—“The turtle-dove is twelve inches long and seventeen in extent; bill black; eye of a glossy blackness, surrounded with a pale greenish-blue skin; crown, upper part of the neck, and wings, a fine silky slate-blue; back, scapulars, and upper wing-coverts, ashy-brown; tertials spotted with black; primaries edged and tipped with white; forehead, sides of the neck, and breast, a pale brown-vinous-orange; under the ear-feathers a spot or drop of deep black, immediately below which the plumage reflects the most vivid tints of green, gold, and crimson; chin pale yellow-ochre; belly and vent whitish; legs and feet coral-red, seamed with white; the tail is long and cuneiform, consisting of fourteen feathers; the four exterior ones on each side are marked with black, about an inch from the tips, and white thence to the extremity; the next has less of white at the tip; these gradually lengthen to the four middle ones, which are wholly dark slate; all of them taper towards the points, the two middle

ones most so. The female is an inch shorter, and is otherwise only distinguished by the brilliancy of her colour; she also wants the rich silky blue on the crown, and much of the splendour of the neck; the tail is also somewhat shorter, and the white with which it is marked less pure."

These birds do not begin their winter migration from any part of the United States until the frost begins to set in; and except it be the states of the extreme north, they do not entirely quit any place during the winter. In the Carolinas and Georgia the woods swarm with them at this season, and the rustling of their wings is heard in all quarters. They are not very timid then; and as they are in numerous flocks very close together, they become an easy prey to the fowler at the very season when their flesh is in the best condition. They move northward in March or early in April, and by this time the large flocks are broken up. "Here," says Wilson, "they commonly fly in pairs; resort constantly to public roads to dust themselves and procure gravel; are often seen in the farmer's yard before the door, the stable, barn, and other outhouses in search of food, seeming little inferior in familiarity, at such times, to the domestic pigeon. They often mix with the poultry while they are fed in the morning, visit the farm-yard and adjoining road many times a day, and the pump, creek, horse-trough, and rills for water. Their flight is quick, vigorous, and always accompanied by a peculiar whistling of the wings, by which they can easily be distinguished from the wild pigeon (*Passenger Turtle*). They fly with great swiftiness, alight on trees, fences, or on the ground indiscriminately; are exceedingly fond of buck wheat, hempseed, and Indian corn; feed on the berries of the holly, poke, buckie berries, partridge berries, and the small acorns of the live oak and shrub oak. They devour large quantities of gravel, and sometimes pay a visit to the kitchen garden for peas, for which they have a particular regard." In different latitudes of the long range of the United States, they of course begin to breed at different times; but in the Middle States they begin in the end of April and beginning of May. Their nests are formed of sticks and very rude; they are always in concealment, but they do not confine themselves to the depths of groves like the eastern turtles, for they nestle in gardens if the trees are close enough, in ivy upon wall, or in some instances under a bush upon the ground. In their habits they are thus very different from the turtles of the east; but the greater number of them are in the woods, and we must allow their unrivalled historian to describe their song in his own language. He mentions that those who wander in the American woods in the spring, will there hear many a singular and sprightly performer, "but none so mournful as this. The hopeless woe of settled sorrow, swelling the heart of female innocence itself, could not assume tones more sad, more tender and affecting. Its notes are four; the first is somewhat the highest and preparatory, seeming to be uttered with an inspiration of the breath, as if the afflicted creature were just recovering its voice from the last convulsive sobs of distress; this is followed by three long, deep, and mournful moanings, that no person of sensibility can listen to without sympathy: a pause of a few minutes ensues, and again the solemn voice of sorrow is renewed as before. This is usually heard in the deepest parts of the woods, frequently about noon and towards evening."

None but a master of the highest order, both as an observant naturalist, and as deeply read in the feelings of the human heart and their sources, would have rendered the song in this strain. Yet, after all, it is rendered according to the manner of men, and not according to the physiology of the bird; for it must be recollected that these notes, sad as is their tone, and mournful as is their cadence, are the epithalamium of the delighted turtle.

Passenger Turtle. In some respects this bird is the marvel of the whole Columbidae race, highly interesting as many of them are, and as all would doubtless be, were we acquainted with their manners. The bird is beautiful in its colours, graceful in its form, furnished to admiration in its powers of flight, and far more a child of wild nature than the Carolina turtle. The especial marvel, however, is in its multitudes—multitudes which no man can number; and when Alexander Wilson lays the wand of the enchanter upon the mighty valley of the Mississippi, and conjures it up to the understanding and the feeling of the reader, with far more certain and more concentrated and striking effect than if it were painted on canvas or modelled in wax, these pigeons form a feature in it which no one who knows can by possibility forget. It is probable that the multitudes may not be more numerous than those of the petrels in Bass's Strait, of which Captain Flinders, who also was a kind of Wilson in his way, gives so graphic a description. But, vast as the multitude of these was, it was only as a passing cloud to the gallant captain; he was not able to follow it up; and, even though he had, the flight of birds over the surface of the sea is lame and storyless as compared with the movements of the unnumbered myriads of those pigeons in the great central valley of America.

None of the names which have been bestowed upon this species is sufficiently, or at all descriptive of it. *Passenger*, the English expression, and "*migratoria*," the Latin name, fall equally short, inasmuch as every known turtle is, to a greater or less extent, migratory as well as this one. The "*swarm*" turtle, the "*flood*" turtle, or even the "*deluge*" turtle, would be a more appropriate appellation; for, as we shall see, the weight of their numbers breaks down the forest with scarcely less havoc than if the tide of the Mississippi were turned against it.

Birds so numerous demand both a wide pasture and powerful means of migration, and certainly these are not stinted in either of those respects. In latitude their pasture extends from the thirtieth to the sixtieth degree, which is upwards of two thousand miles; and the extensive breadth in longitude cannot be estimated at less than fifteen hundred. Three millions of square miles is thus the extent of territory of which the passenger turtle has command; and that territory has its dimensions so situated as that the largest one is the line upon which the birds migrate.

These birds in so far resemble the rock pigeon, that they are social both in their breeding-places and on their migrations; but we are not aware that a proper experiment has been made to ascertain whether this sociality of theirs could be made the basis of domestication. As the case stands at present, indeed, there is but little temptation to make such an experiment, because their numbers are so great, and they can be procured, and often actually gathered from the ground in such abundance, that there is little or no

temptation whatever to rear them artificially. Their flesh, too, is not of the very best quality, and their numbers and voracity are such as to render them little short of nuisances upon the cultivated grounds. Even in Canada their numbers are so great, and the ravages which they commit upon the cultivated ground so extensive, that instances are recorded in which the Bishop has been seriously and earnestly implored to exorcise them by "bell, book, and candle;" that is, to cast them out of the land by the same means whereby unclean spirits, in the days (happily now gone by) when they were troublesome to individuals, were cast out of their possession of the bodies of men and women. As the possession in the case of the individual human beings was, according to our modern notions, quite imaginary, it is highly probable that the exorcism of bell, book, and candle, which was also imaginary, might produce the desired effect. But, as the passenger turtles were material beings, and not spiritual, we rather suspect that the Bishop had the good sense not to try the experiment upon them; at least La Houtan, who records the matter, is perfectly silent as to the success or failure of the experiment.

Before we begin to give a short outline of the manners of these extraordinary birds, it may be as well to describe their personal appearance. They are birds of particularly handsome form, with long and pointed wings, and the tails also particularly long and wedge-shaped, the lateral feathers being not more than half the length of the central ones. The male bird is sixteen inches long, of which, however, the tail occupies a half, or at least nearly so; the stretch of the wings is two feet, so that, altogether, the flying feathers are very large and powerful in proportion to the size and weight of the bird, and consequently well suited to its migratory habits; the head, upper part of the neck, and chin, are of a fine slate-blue colour, paler on the chin than the other parts, but altogether forming a well-marked head; the back, rump, and tail-coverts, are deep slate-grey, dotted on the scapulars with a few dusky marks, and tinged with brown over the insertion of the wing; the greater coverts of the wings are light slate colour; the quills are blackish, the primaries margined and tipped with brownish white; the tail is long, and, as has been said, much wedge-shaped by the feathers increasing in length from the sides to the middle; the two middle feathers are plain black; the other five, on each side, are bluish at their bases, passing into a sort of greyish-white toward their tips, and marked with a black spot on the inner web of each near the base, and with a rust-coloured one still nearer; the bastard wing is black, and there are some black spots on the wing-coverts; the throat, breast, and sides, as far as the thighs, are very pale reddish chestnut, passing into a pale wine-red on the lower part of the breast, and also on the feathers of the thighs; the belly and vent feathers are white; the lower part of the neck behind, and the sides of the same, are crimson, inclining to purple, but with changeable glosses of green and gold; the bill, which is slender, but has the upper mandible considerably arched, is black, and the high naked skin in which the nostrils are pierced is nearly of the same colour, and forms a rounded protuberance; the irides are brilliant reddish orange, and the small portion of naked skin around the eyes is deep purple; the contrast of these colours, with the delicate slate-blue in which they are

NAT. HIST.—VOL. III.

set, gives the eye a very striking and expressive appearance; the naked parts of the tarsi and the toes are clear lake-red, streaked with white. The female is half an inch shorter than the male, and an inch less in the stretch of the wings; the breast is brownish ash; the upper part of the neck slightly ash-coloured; the changeably-coloured portion of the neck is of smaller extent, and not nearly so brilliant; the tail-coverts have a brownish tinge; and all the other parts of the plumage, which resemble those of the male in their disposition, are duller in the tint, and have more or less of brown in them. Still both sexes are beautiful birds. Their value, in an economical point of view, is not, however, in any way equal to their beauty or their numbers. The flesh of the old ones is dark, dry, hard, and unpalatable, as is very generally the case with birds which are much on the wing; but the young, or "squabs," as they are called by the inhabitants of the United States, are remarkably fat; and as, in the places where the birds congregate, they may be obtained without much difficulty, this fat is obtained by literally melting them, and used instead of lard, to which, however, it is inferior, as there is a rankness of flavour about it. As they nestle in vast multitudes at the same place, their nesting-places have many attractions for birds of prey, which indiscriminately seize upon both the old and the young. The nests are very flimsy fabrics, and, though they are placed in the very closest trees, the young may readily be seen by those who pass into the forests under them. The eggs, like those of most of the pigeon tribe, are usually two in number; but the number of birds at one nesting-place is so great, that the young, when they begin to branch and feed, literally drive along the woods like a torrent. They feed upon the fruits, which, at this time, they procure in the middle height of the forests, and do not venture upon the open grounds. The nests are far more closely packed together than in any rookery, and are built one above another from the height of twenty feet to the top of the very tallest trees. Wilson says—"As soon as the young were fully grown, and before they left the nests, numerous parties of the inhabitants, from all parts of the adjacent country, came with waggons, axes, beds, cooking utensils, many of them accompanied by the greater part of their families, and encamped for several days at this immense nursery. [This nursery was near Shelbyville, in Kentucky, forty miles long and several miles in breadth]. Several of them informed me that the noise in the woods was so great as to terrify their horses, and that it was difficult for one person to hear another speak without bawling in his ear. The ground was strewed with broken limbs of trees, eggs, and young squab pigeons, which had been precipitated from above, and on which herds of hogs were fattening. Hawks, buzzards, and eagles, were sailing about in great numbers, and seizing the squabs from their nests at pleasure; while, from twenty feet upwards to the tops of the trees, the view through the woods presented a perpetual tumult of crowding and fluttering multitudes of pigeons, their wings roaring like thunder, mingled with the frequent crash of falling timber; for now the axemen were at work cutting down those trees which seemed to be most crowded with nests, and seemed to fell them in such a manner that, in their descent, they might bring down several others, by which means the falling of one large tree sometimes produced two hundred squabs, little inferior in

G G

size to the old ones, and almost one mass of fat. On some single trees upwards of one hundred nests were found, each containing *one* young only—a circumstance in the history of this bird not generally known to naturalists. It was dangerous to walk under these flying and fluttering millions, from the frequent fall of large branches, broken down by the weight of the multitudes above, and which, in their descent, often destroyed numbers of the birds themselves; while the clothes of those engaged in traversing the woods were completely covered with the excrements of the pigeons."

This is a scene to which we are aware of no parallel in the nesting-places of the feathered tribes, and certainly there is nothing bearing the slightest approximation to it among the birds of the British islands. In many of those detached isles, especially of the north, such as Sula's Skerry and its stack, and Cradle Island in Shetland, where sea-birds "most do congregate" for the rearing of their young, it is not easy for the adventurous traveller to get a foot-fall without breaking an egg; but these birds build on the rock, and their weight never injures its stability; nor are we aware of any other part of the world where the trees are broken down by the multitudes of birds which nestle in them.

Where the birds roost for the night, although they do not breed, and they are understood to have select places for this purpose, the congregating, though not permanent, day and night, is often as great and as destructive of the forest. The native Indians rejoice in a breeding or a roosting place of the migratory turtle, as one which shall supply them with an unbounded quantity of provisions, in the quality of which they are not particularly chary. Nor are these roosting places attractive to the Indians only, for the settlers near them also pay them nocturnal visits. They come with guns, clubs, pots of suffocating materials, and every other means of destruction that can well be imagined to be within their command, and procure immense quantities of the birds in a very short time. These they stuff into sacks, load their horses with, and so return home.

On the subject of the migration of these birds we have nothing to add to the following quotation from Wilson:—"These migrations appear to be undertaken rather in quest of food than merely to avoid the cold of the climate; since we find them lingering in the northern regions, around Hudson's Bay, so late as December; and since this appearance is so casual and irregular, sometimes not visiting certain districts for several years in any considerable numbers, while at other times they are innumerable. I have witnessed these migrations in the Genesee country, often in Pennsylvania, and also in various parts of Virginia, with amazement; but all that I had then seen of them were mere straggling parties when compared with the congregated millions which I have since beheld in our western forests, in the states of Ohio, Kentucky, and the Indian territory. These fertile and extensive regions abound with the nutritious beech nut, which constitutes the chief food of the wild pigeon. In seasons when these nuts are abundant, corresponding multitudes of pigeons may confidently be expected. It sometimes happens that, having consumed the whole produce of the beech trees in an extensive district, they discover another, at the distance perhaps of sixty or eighty miles, to which they regularly repair every morning, and re-

turn as regularly in the course of the day, or in the evening, to the place of their general rendezvous, or, as it is usually called, the roosting place. These roosting places are always in the woods, and sometimes occupy a large forest. When they have frequented one of these places for some time, the appearance it exhibits is surprising. The ground is covered for several inches with their dung; all the tender grasses and underwood destroyed; the surface strewn with large limbs of trees, broken down by the weight of the birds clustering one above another; and the trees themselves, for thousands of acres, killed as completely as if girdled with an axe. The marks of this desolation remain for many years on the spot, and numerous places could be pointed out where, for several years after, scarce a single vegetable made its appearance."

We have no more space for entering into the details of the habits of those very extraordinary pigeons. There is little doubt that they could be domesticated, at least as much as the common house-pigeon is domesticated; though, as their natural habit is to nestle in trees, it is very doubtful whether they could be made to make a pigeon-house their home. The fact of their being found lingering as stragglers during the winter, in latitudes where the temperature is considerably below zero, is sufficient proof that they would bear any climate of the eastern continent. It may seem that the dark colour, dryness, and hardness of the flesh of the old birds, would render them of comparatively little value in an economical point of view, but no positive conclusion can be drawn from the quality of a bird's flesh in a state of nature, as to what might be its qualities were it domesticated. It is the violent and frequently-repeated labour to which they are subjected that hardens the muscles of birds in a state of nature; and if the birds are brought up from their earliest age, and kept upon rich pastures where they have occasion to use the wing but little, the tenderness and also the flavour of their flesh are greatly improved. This has been established by actual experience, in the case of the pigeon-house pigeon and the wild-rock, the second being greatly inferior to the first, though dressed in precisely the same manner, and served up at the same time, which prevented any part of the decision from resting upon the judgment of mere memory, which is never an exact subject of comparison with present sensation. Even in the case of pigeon-house pigeons, there is a considerable difference in the quality, depending on the kind of country in which the pigeon-house is situated. If that is a poor district, where leguminous and other farinaceous seeds are few and of small size, and where consequently the birds must use the wing much in procuring their subsistence, then the flesh is hard and in small quantity, and has its flavour sharpened almost to bitterness. On the other hand, if the pigeon-house is in a rich country, where cultivated legumes and grain, the larger wild vetches and beech wort, are to be had in abundance, with comparatively little labour, then the flesh is not so dark in the colour, it is much more abundant in quantity, more juicy, and though not so pungent yet more agreeable in flavour. The same law holds in the flesh of all animals, and of course the quality may be carried to an extreme both ways. Increase of fatigue on the part of the animal invariably produces hardness, dryness, and pungency of flavour, and if carried to excess the flesh ceases to be eatable. In a similar

manner increase of ease relaxes the muscles, and swells and softens their fibres, so that they become tasteless, and when this is carried to excess they become noxious from their insipidity, and do not stimulate the stomach. This is a principle that runs through the whole of living and growing nature, and applies to vegetables as well as animals; and there is a fine moral in it, for it is a practical demonstration that the middle course is always the best. When these circumstances are considered, there seems little doubt that, at least after a generation or two, the passenger turtle might become as desirable for the table as the common pigeon; and, as it is so much more elegant and beautiful, it would make one of the finest rural ornaments in the country. Nor would it be at all amiss to introduce these birds into our forests. It seems indeed somewhat strange that the forests, which are in some respects the richest of our pastures, should never hitherto have been turned to any useful purpose in the way of maintaining birds. The only really good forest bird which we ever had—the wood grouse, or *capercaillie* as it was called in the Highlands—has been exterminated; and all that remains is the wood pigeon. Forests are in themselves highly interesting; there are thousands of acres in the three kingdoms which would be much more profitably applied to the growth of timber than to any other purpose; and, were they so applied, there is no question that it would add greatly to the value of the remaining part of the land, inasmuch as it is, in a great measure, to the bare places, where trees alone would be profitable, that we owe the burning drought of our summers, and the extreme cold of our winters, both of which are often highly disastrous. Now if we had the forests, and it is a disgrace to the proprietors of the soil that we have them not, there is no reason why they might not be peopled with every forest bird, whether useful or ornamental, that could stand the climate. The birds of America are especially adapted for this purpose, because the extremes of the seasons are more wide there than they are with us; and had it not been for the barbarous and most unpatriotic havoc which the bores of the back woods have committed on the wild turkeys, our forests might in time have been stocked with them. We must leave the subject, however, and notice one or two more of this section of the pigeons.

Of these we shall notice only two species, one of them a native of Southern Africa, and the other of New Holland. They agree in their general structure with the long-tailed turtles of America; but they depart further from the colours of the European pigeons. They are birds of very small size, slender and elegant in their forms, very well winged, and have the tails very long and acutely wedge-shaped, with the two central feathers projecting far beyond the rest, and narrowed toward their tips. Like the passenger turtle of America, their tails consist of twelve feathers. It has been proposed to make a separate subgenus of them, but we are convinced that this would be merely adding to the number of words without increasing the quantity of knowledge, and thereby rendering the study of ornithology more intricate.

The Cape Turtle. This species, as its name imports, is of Southern Africa. It is very small, but exceedingly handsome. Its length is about seven inches, but more than the half of that is occupied by the tail. The bill is of moderate size, straight in the

greater part of its length, but with the tip of the upper mandible curving over that of the under one, and it is of a yellowish-brown colour. The wings are of moderate length, but not so long in proportion as those of the passenger turtle; they are pointed, the second quill being the longest, and both the first and the third being considerably shorter. Both the tarsi and the toes are short, and the claws are blunt and nearly straight. From this structure of the feet it follows as a matter of course, that the chief labour of the bird, namely, the finding of its food, must be upon the ground, though the shortness of the tarsi must make it a slow walker, as the whole of the pigeon tribe, like the gallinaceous birds, walk with the alternate foot and do not hop. One of the most striking marks of colour in this bird is a large patch of deep black, which passes over the forehead, the sides of the head as far as the eyes, the chin, throat, foresides of the neck, and the breast, extending in breadth upon the last, and rounded at its termination. The top of the head, which is much flatter than in most of the species, the sides of the neck, the lower part of the breast, the flanks, and the smaller coverts of the wings, are pale French grey. The rest of the under parts and the thighs are white. The clothing feathers on the upper part are brownish-grey, and so are the nape and hind part of the neck. The feathers of the wings are brown with an orange tinge, gradually deepening toward the primary quills, and passing into black. On the wing there are two well-marked spots of deep brownish purple, with metallic reflections; the under coverts are orange-brown; two black bars cross the feathers of the rump, and between them there is a stripe of pale grey; the basal half of the two central feathers of the tail is brownish-grey, and thence they gradually deepen into black. The other feathers are bluish-grey at their bases, and pale grey for a small portion of their tips, with a black band between that and the former colour. They are rounded at their tips, and graduated, the difference in their length diminishing as the external ones are reached. The feet are yellowish-brown, the same as the bill.

It is necessary to pay particular attention to the difference between the male and female of this bird; because inattention to this, or seeing only the one sex and not the other, has led different naturalists to describe the most conspicuous marking of them in very opposite colours. The frontlet and gorget, which are black in the male, are pure white or nearly so in the female. The other colours are distributed in the same manner, but they are much paler in their tints. The young males have the throat and breast brown with white bars, and black bars on the back and wing coverts, the top of the head brown, and the chin white. On account of these differences of colour, they also have been sometimes mistaken for a separate species, and we believe that there are some books in which the species taken generally are described as having the mottled colour.

This is a very interesting bird, from its being, in its character and habits, a member of the pigeon family, and yet being very little weightier in the body than a sparrow. Though it is very generally distributed over Africa southward of the desert, and even down to the valley of the Nile as far as Nubia, very little is known of its habits farther than that it follows the general law of the other turtles, by nestling in trees, and seeking its food upon the ground. The eggs are

understood to be two in number, of a white colour, nearly transparent, and so delicate that they can hardly be touched without being broken. The common English name of Cape turtle is very inapplicable to this bird, and the French name of Hottentot turtle is still more so, because the whole Cape territory is but a fraction of its pasture, and the country of the Hottentots is of course a still smaller one.

The Macquarrie Turtle. This is an Australian species, and would have been more correctly named if it had been called after its country, and not after Governor Macquarrie. In size and shape it very much resembles the turtle of Southern Africa last described, but the markings of its colours are different. Notwithstanding this, it may be the same identical species; for it is a pretty general law among birds that those in which the sexes and the old and the young differ much from each other in colour are the most liable to have their colours altered by difference of climate. This one has the whole of the upper part brownish, and the head, neck, and breast bluish-grey; the smaller coverts of the wing are also brownish, but spotted with white, each spot surrounded by a black circle; the greater coverts are ash colour, but spotted in the same manner as the others; the quills are reddish-brown; the tail-feathers are similar in shape to those of the preceding species, the central ones are blackish-brown, and the lateral ones bluish-ash colour; all the under part below the grey on the breast is pure white; the bill is black, the naked space round the eyes orange, and the feet reddish. Differences of colour in those naked parts of the bird are much more specific than differences of the plumage; but even they are not altogether to be depended on. So far as the manners of this species have been observed, they appear to be the same as those of the African bird, making allowance for the difference of the countries which they inhabit.

Thus it may be said, that there are turtles in three distinct localities: first, southern Europe, northern Africa, and western and central Asia; secondly, America, chiefly the northern part of it; and thirdly, Southern Africa and Australia; and it is not a little remarkable that those of the north-west and south-east should resemble each other much more than either of them does the intermediate ones.

GROUND DOVES. These form the third section of the great family of pigeons; but, as in the others, the line of separation is by no means clear and definite; and, notwithstanding the fondness which many naturalists show for extreme minuteness of division, there is a distinct character which runs through the whole family, from the most lofty inhabitant of the tall forests, to the most lowly dweller upon the ground. We have seen that the pigeons and the turtles are chiefly ground feeders, and some of the turtles, we may say, are exclusively so, though they all nestle at some elevation above the ground, except the rock pigeon, and some of the others when there are no trees conveniently situated for them. The ground doves very generally, if not exclusively, find their food upon the ground, but very many of them perch, and it is probable (for we know little of the habits of most of them) that not a few of them nestle in trees, or, at all events, in bushes. Generally speaking, they are birds having their flying feathers less developed than those of the other sections; because, of their terrene habit, they have been described as approximating the gallinaceous birds; but though they

do partially correspond with these in this particular habit, they, in their essential characters, and in the air and aspect of their bodies, differ materially. Their clothing feathers are also much looser, and in one species, which differs much in its general aspect, the feathers are much produced, and hung loosely apart from each other. Although, as we have said, many of them perch, and some probably nestle in trees, yet they are much better fitted for walking than any others of the family. Their tarsi are longer and stronger than in these, and their feet are by no means well adapted for grasping, the claws being straight and blunt. Their flight is low and fluttering, though not so much so as in the gallinaceous birds; and they flit from place to place upon the wing, but always alight at short distances, and range the spot where they alight on foot. They are thus adapted to peculiar localities; namely, open plains interspersed with bushes and thickets, and consisting alternately of barren and fertile spots. In this respect they are certainly intermediate between the other divisions of the family and the gallinaceous birds. Even those of the former, which most habitually feed upon the ground, can dash rapidly on the wing over considerable distances; while the gallinaceous birds very seldom have recourse to the wing, unless when they are alarmed, or flying to their perches. This intermediate habit of the ground doves determines in some measure their localities. The prairies of North America are very often alternate hummock and bare surface. It is the same in all countries within the tropics, at least for a considerable period of the year. Hence, North America is, we believe, the only temperate part of the world in which ground doves occur, and they occur also in the south and south-east of the old continent. There are none in Europe, and, we believe, there are none in Asia northward of the mountains which lie between Persia and Upper India and the central regions.

In consequence of the dissimilarity of size and colour in these birds, authors have subdivided them into various groups; but the grouping does not convey much information, and our space will allow us to notice only a few of the most strongly marked of the species.

American Ground Dove. Though this bird is found in temperate America, it does not reach so far north as Virginia. It is, however, abundant in the southern states, and also in the West India islands. In the West Indies it is sometimes confined in cages. The French planters give it the dignified name of *Ortolan*; the bird is most numerous in the islands on the coast of Carolina and Georgia, where they fly in coveys of from fifteen to twenty. They are most commonly met with in the open fields and plantations, which they prefer to the forests; they are generally seen on the ground; and though scared off, they only fly a little way and again alight. They feed on rice, seeds, and berries of the toothache and other trees, under whose shade they are almost sure to be met with in the proper season. Their flesh is esteemed as excellent food. Their note is a low plaintive one, which is accompanied by the usual gestures of their tribe. They are migrant birds, and, on the approach of winter, retire to the islands and to the more southerly parts of the continent, and return to their former haunts about the beginning of April. They are of a more delicate and slender form, and less capable of enduring the severity of cold than either of the other two species met with

in the United States, both these being found in the northern parts of Canada, as well as in the temperate climate of Florida.

The length of the ground dove is six inches and a quarter; the bill of a yellow colour, with a black tip. As is usual with the genus generally, the nostrils are covered with a protruding membrane; the iris of the eye is orange red; the breast, throat, and sides of the neck are of a pale wine-coloured purple; the feathers are deeply marked by semicircular margins, those on the throat being dusky blue in the centre; the crown and back of the head are of a rich pale blue, intermixed with purple, and marked with detached spots of a glossy blue, with reflecting tints of purple; the belly is pale wine-coloured brown, becoming dark cinereous towards the vent, where the feathers are margined with white; the wing-quills are dusky at the outsides and the tips; but the whole interior varies, and the lower sides are of a rich red chestnut, which appears a little below their coverts; the tail, which is rounded, consists of twelve feathers, the two middle ones being cinereous brown, and the rest black, margined and tipped with pure white; the feet and legs are yellow. The back and tail-coverts of the female are of a mouse colour. She has scarcely any of the wine-coloured tinge on the breast and throat, nor of the light blue on the back of the head; the throat is spotted with a dull white, pale clay colour, and dusky; the sides of the neck are of the same colour, and the plumage is strongly marked; the breast is of a cinereous brown colour, faintly tintured with purple; the scapulars are strongly marked with big drops of a dark purplish blood colour, which reflects fine and delicate tints of blue; the rest of the plumage differs very little from that of the male.

Rust-coloured Ground Dove. This is a South American species, of diminutive size, but a very neat and handsome bird. It inhabits the open ground rather than the woods, though it always perches when at rest, and nestles in a bush or branchy tree near the ground. Paraguay and Brazil are the chief places of its residence, and it is not found in the richly-wooded districts by the rivers, or upon the mountain ridges. It is a very familiar little creature, and does not hesitate to come close to the dwellings of the inhabitants in search of its food. It is also quite at home, and breeds freely in a state of confinement, though it cannot be domesticated so as to leave its home and again return to it. One might expect this from its habits in wild nature, because it is not very social at any season. In the breeding time the pair live quite solitary, and at no season of the year are more than half a dozen seen together, and these are understood to be the old pair and two broods. Its plumage consists principally of two colours. The head and a small portion of the upper neck all round are ashen grey, with a tinge of purple on the front, and reddish white on the throat; the rest of the plumage is orange brown, passing into dark purple brown on the under part; there are a few streaks of black on some of the coverts of the wings, and the bastard wing and under wing-coverts are of the same colour; the principal quills are dark brown inclining to black; the quills are remarkably broad, and the inner web forms a projecting lobe about the middle of its length; the tail-feathers are the same colour as those of the wings, with the exception of the two middle ones, which are the same colour as the back, only a little

lighter in the shade; the bill and naked skin round the eye are bluish grey, and the tarsi and toes pale purplish red. The female has the head very dull grey, and the under plumage the same; the back and all the upper part are dull brown with reddish blotches; and the wings, tail, and naked parts are coloured the same as in the male birds; the length is very little more than six inches.

Picui Ground Dove. This species is an inhabitant of the same countries as the last mentioned, and its habits are nearly similar, but it is rather larger and differently coloured. Its length is seven inches and a quarter; the upper parts are brown, and the front and sides of the head whitish; the quills are blackish brown, and the wings are mottled over with small spots of brilliant blue; the middle tail-feathers are brown, and those next them are brown with white tips, except the two lateral ones, which are white altogether; the under parts are whitish, clouded with brown on the neck, and wine colour on the breast; the naked space round the eye is blue, and the bill and feet reddish.

There are many other species of small ground pigeons in South America; but the habits of all are so nearly the same, that the specimens we have mentioned must suffice for the whole.

Bronze-winged Ground Dove. This is a very handsome species, remarkable for the variety of its colours, and for the distinctness with which every individual feather comes out, in consequence of the margin being in all cases paler than the middle part of the feather. It is also remarkable for the brilliant glosses which appear on some of the feathers. It is a much larger bird than the two species which we have mentioned, and its wings are more powerful and more pointed than those of any of the ground doves of America. It is about fifteen inches in length; and the bill, which is blackish at the tip and reddish toward the base, is about an inch in length, which is long in proportion as compared with many of the pigeon tribe. The forehead is whitish and a streak under the eye and the chin are pure white; the top of the head is reddish brown, surrounded by a margin of deep red; the cheeks and sides of the neck down to the scapulars are blackish grey, which becomes paler, and has a purple or lilac tinge on the throat, and breast; the rest of the under part is grey, glossed with greenish purple; the clothing-feathers on the upper part are blackish brown, passing into pale orange brown on the margin of each feather; the coverts of the wings are bluish grey, and each feather has upon its exterior web a spot, of which it is impossible to describe the colour, because it varies in every tint, from intense blue to deep red, according to the angle on which the light falls upon it; the upper plumage, generally speaking, has this property, though brown and green are the limits of the colours on the back. In consequence of these variations of colour, it is impossible to give a pictorial representation which shall be like this bird in the particular light in which an observer may see a specimen. The quills are brown, passing into orange red on the margins of their inner webs; and the bastard wing and under coverts of the wings are of the same colour; the tail is grey in the principal colour, but crossed by a band of black near the tip; the tarsi and the toes are dark red.

It is a native of Australia, of New Guinea, and of various other islands in the eastern sea. It is a bird.

of sterile places, being found on the arid plains which contain only a few bushes and stunted trees. It feeds upon the berries of some of the singular shrubs which occur in these countries, especially upon those of *Lissanthe*, one species of which, by the way, is the only shrub in Australia which bears any thing like an eatable berry. The resting-place is either in a hollow tree near the ground, or on the ground itself, and hollow trees are understood to be far more abundant in Australia than in any other part of the world. It makes scarcely any nest, the eggs are two, and of a white colour. During the breeding time, which of course is in our winter, as that answers to the Australian summer, the pairs never part, and are much attached to each other; and it does not appear that at any time these birds flock. The note of the male is decidedly that of the pigeon tribe, and it is so loud as to be heard at a considerable distance. Though these birds are generally seen upon the ground, yet they perch during the night on trees or bushes, but never at any very great elevation. It appears that they are in so far migratory, moving southward, or into colder latitudes, during the summer, and northward into warmer ones during the winter; for though they are common enough in the neighbourhood of Sydney during the summer half year, or from September to February according to the calendar, they disappear during the remaining months. They are exceedingly beautiful birds; but it does not appear that they could be domesticated. We shall now notice one or two of the ground doves of southern Africa and the warmer parts of America, which have still more of the ground character than those which we have already noticed, though they do not, as has been alleged, make the slightest approach to the gallinaceous birds, either in their appearance or habits. It is true that their wings are hollow and round, and their tarsi long and strong, so that they are incapable of long flight, though very dexterous at rising, and they can run with much celerity. In consequence of this, they have been called pigeon pullets, and sometimes pigeon partridges; but these additions to the names are inaccurate, inasmuch as the bill and head, and indeed the whole expression of the bird, are decidedly those of a pigeon. They live chiefly upon the ground, and sometimes nestle there if they cannot find low bushes for that purpose. Their domestic establishments have not been much observed, but it is generally understood that each hatch consists of only two eggs. This point is not, however, absolutely ascertained. But, though they feed habitually upon the ground, and sometimes nestle there, they generally, if not always, perch for repose; and though their wings are short and rounded, they are still decidedly pigeon wings. We shall notice two or three of the species.

White-bellied Ground Dove.—This species is found in South America, and also in Jamaica, and various other of the West India Islands. Its length is about twelve inches. The upper plumage of the body is brown, glossed with a greenish tinge; and the under plumage is white, shaded with purple red on the breast and fore part of the neck. The forehead, chin, and throat, are bluish white; the top of the head and the occiput are greenish grey, but purple in some lights. The sides of the head, from the eyes downward, and the back of the neck, are deep purple red, with rich reflections of lilac and golden green. The roots of the quills, and under coverts of the wings, are pale

yellowish brown. The middle tail feathers are greyish brown, and the three exterior ones on each side are grey, with white tips. The bill is black, and the feet reddish. The claws are short and blunt, indicating the habit of the bird as seeking its food upon the ground, though it generally perches upon low bushes or the lower branches of trees for repose. Its food is wholly vegetable, consisting of the seeds of grasses and other plants. It runs with much more celerity than any of the tree or rock-building pigeons, but it is not so decidedly a dweller in the arid places as the eastern species last mentioned. It is generally found in those bushy tracts which are intermediate between the bare plain and the forest, and it picks up more of its food after that has dropped on the ground than when it is on the plant or bush.

Copper-coloured Ground Dove.—This is another inhabitant of the warmer parts of South America and the West India Islands, but it differs considerably from the former, being considerably smaller in size, and inhabiting different localities. Its pastures are on the elevated and rocky mountains; and as food for it is but thinly scattered there, it is endowed with great swiftness of foot. But though it runs something after the manner of a partridge (and the inhabitants of Jamaica call it the mountain partridge), it always perches on a bush or low branch of a tree when it reposes. It seldom takes the wing except when alarmed, and then its flight is low and fluttering, and performed with a great deal of noise. It cannot continue long on the wing; but when it is pursued it alternately flies and runs, and, as is the case with many ground birds, it flies in one direction and runs in another, in order to throw the pursuer out. It generally nestles upon the ground, under a bush, or in the shelter of a projecting piece of rock, but its eggs are understood to be only two. It is reported that the young are much sooner able to provide for themselves than the young of those pigeons which are better winged; and this is in strict accordance with the general analogy, or the general principle, that running birds are always sooner able to shift for themselves than flying ones, which is always more the case in proportion as the birds are more upon the ground, their pastures more barren, and their food consequently more laborious in the finding. One cannot help admiring the beauty of this adaptation, simple though it be; for otherwise the decidedly ground bird, which is appointed to gather in the scanty harvest of a comparative desert, would not be able to carry a sufficient quantity of food to the nest for the supply of its young. In consequence of this the instinct of maternity is modified in such birds; and the mother, instead of bringing food to her young in the nest, is instructed by nature to lead them to the places where food is to be found. It does not appear that even this dove, which has probably a more decidedly ground habit, and a less productive pasture than any other of the family, comes out of the shell so completely matured for running as a pullet or a partridge, but still it differs remarkably from those species of the family which depend much upon the wing.

The copper-coloured ground dove is about nine inches in length. Its bill is rather short, and its tarsi comparatively long, and both are of a red colour. A portion of the upper mandible towards the face is thickly beset with very small feathers. The head, neck, and whole upper part, are bright orange, but glossed with reflections of rich purple, which give it

the coppery appearance implied by the name. The throat is reddish white, and so are the fore neck and breast, but the latter is glossed with purple, and the colour of the rest of the under part is pale and dull brown, slightly washed with purple red.

White-fronted Ground Dove.—This is a much larger species than any of the ground doves of the American continent. It is a native of Africa, and though by no means a rare bird it is difficult to be seen in consequence of its habit of concealing itself among the bushes. It is about eleven inches in length. The forehead, the cheeks, and the throat are white or whitish, from which it gets the trivial name. The clothing plumage on the upper part is brown, but glossed with green reflections, which come out in certain lights. The under plumage is orange brown washed with purple, but not showing reflections as the upper part does. The top of the head and the neck are of the same colour as the under parts, but with green reflections, particularly strong on the sides of the neck. On the lower part of the neck behind there is a half collar of purple black, with golden green margins to the feathers. The two middle feathers of the tail are brown, and all the remaining ones are black at the bases, and bluish grey at the tips. The bill is bluish black, and the tarsi and toes brown red. Though not a gaudy species this is an exceedingly beautiful one, and it is one which is sought after with some avidity, the more so that it cannot be obtained without considerable difficulty. As is the case with the whole section of the ground doves, it feeds upon the ground, or upon the seeds of herbaceous plants, and the berries of low bushes, but its resting place is in the brush or close shrubbery which lies between the dry karros and the rich forests on the Orange River. It is understood to be especially a bird in the Nimagua country, at the mouth of the Orange River, which is one of the best districts from which to obtain all the choicer birds and mammalia of Southern Africa. Its flight is low and fluttering, somewhat resembling that of the *Gallinidæ*; but notwithstanding the lowness of its flight it is extremely difficult to obtain, because it glides into the thick bushes with so much rapidity as to elude the aim of the keenest sportsman. It nestles in the bushes, and also resorts to them always when it reposes. Its eggs are described as being only two in number in one hatch, and the nest is rudely constructed of a few sticks at a very little above the surface of the earth. Some writers on birds have described this as an American species; but there is not in any part of America or its islands any ground dove of the same size as this one, or in the least resembling it in the markings and glossings of its colours.

We shall now notice one or two species, which, though they preserve the pigeon character in the bill, the head, and all the essential parts of their organisation, are even more terrestrial in their habits than those to which we have alluded. According to some writers, these pigeons form a nearer approach to gallinaceous birds than any others of the family, by which nothing more is meant than that a resemblance can be traced by imagination between them in a few more particulars. These resemblances, or "affinities," as the sages term them, put one strongly in mind of Fluellen's proof of the identity of Macedonia and Monmouth:—"Look you, there's a river in Monmouth, and I'll be pbound there's a river in Macedonia, and they call it Wye at Mon-

mouth, and it's out of my prains what they call it in Macedonia; but it's as like as my fingers to my fingers, and there's saumons in them poth." These pigeons live upon the ground, but roost in low bushes, and their eggs are not confined to two in a hatch, but are understood to reach as many as eight or ten. The nest is on the ground, and the birds are very soon able to pick up their own food, though it is some time before they are sufficiently winged for being capable of flying. They still preserve so much of the pigeon habit as to roost on low bushes, which is a decided distinction between them and the grouse department of the gallinaceous family, which they are supposed most nearly to resemble. Like those last mentioned, they are found in America and in Southern Africa, and one very peculiar species occurs on the Eastern Islands.

Blue-headed Ground Dove.—This is a very beautiful species, a native of the West India Islands, where it is by no means rare, and also of some of the warmer parts of continental America. It measures about eleven inches in length, and weighs about the same as our common partridge. The general plumage is deep brown, with a shade of purple; the throat, fore neck, and breast, are black, with a white margin between it and the brown; the head is clear and rich azure blue, and there are three or four lines of feathers of the same colour extending from the gape as far on the sides of the neck as the black extends; between these and the eye there is a patch of pure white, which shows off the blue to great advantage; the feet are red; and the bill is reddish at the base and grey at the tip. This bird is generally seen upon the ground, where it runs with great celerity; but it does not readily take the wing, nor is it very dexterous in flying, as it is obliged to move its wings rapidly, and with a great deal of noise and flutter, as if it were out of its proper element. When upon the ground its attitude something resembles that of a turkey or a guinea fowl; but still its essential characters are those of a pigeon.

Carunculated Ground Dove.—With the lovers of affinities this bird makes a still nearer approach to the *Gallinidæ* than the former, inasmuch as there are crimson wattles pendant from the neck. These, however, have no similarity to the wattles of the common domestic cock; and the head, bill, and general air of the bird, are decidedly those of a pigeon. The crimson naked skin surrounds the bases of both mandibles of the bill, that from the upper mandible passing backwards, and surrounding the eye, and that from the lower passing, in one branch, two-thirds across the sides of the neck, and in another forming a loose wattle on the breast.

The full-grown bird measures about eleven inches in length, and is rather thick in the body; the head, cheeks, and neck, as far as the shoulders, and also the coverts of the wings, are grey, margined with a fine line of white, which makes the individual feathers tell very conspicuously; the under part, and also the upper tail-coverts, are white; the tail is reddish brown; and the quills of the wings have a shade of purple on them. The female is of the same size as the male, and marked with the same colours; but she entirely wants the bright naked skin on the head by which he is characterised. There are certainly some resemblances between this species and the gallinaceous birds, though there are others in which it more resembles the pigeon family, of which its organisation

clearly shows that it is a member. The eggs are six or eight in number, which answers to a gallinaceous bird rather than to a pigeon. The young are covered with down when they break the shell, and the parent birds gather them under their wings. Thus far there is a slight resemblance, but here it ends. The birds pair, which the true *Gallinidæ* never do; and the male and female sit alternately on the eggs, and pay equal attention to the young, which is not the case with any of the gallinaceous birds. Indeed, in all the essentials of their character, these birds are as distinct from the gallinaceous birds, and as decidedly pigeons, as the best-winged and most aerial of the family.

The wattled ground dove is a native of Southern Africa, most abundant in the Nimagua country, which, as we have already stated, is the grand natural museum for the animals of Southern Africa. They are less exclusively vegetable feeders than some of the others, and readily eat insects and worms as well as seeds and berries; and it is understood that the young are at first fed upon animal substances, and that they soon learn to pick up their own food, which is of a miscellaneous character. When the breeding time is over they assemble in packs, but they always separate in pairs, and each pair dwells apart during the breeding season.

Nicobar Ground Dove. The common name of this species is incorrect; for, instead of being confined to the small islands of Nicobar, it is pretty generally distributed over the whole of the Oriental archipelago. It is a beautiful bird, and remarkable for the length and apparent looseness of all its plumage, with the exception of the quills and tail-feathers, which preserve the firm character belonging to the pigeons. It roosts and nestles in trees, though the nest is generally near the ground, and the young are very soon able to find their own food.

It is a very beautiful bird, and one of which it is scarcely possible to describe the colours. The clothing-feathers are one colour, namely, deep bronze green, but, as the light falls differently upon it, this shows every shade of colour from golden yellow to intense purple. The feathers on the head and neck are loose and silky; and the clothing, on the upper part of the body especially, has the feathers very distinct; the tail is white, and the quills are bluish black. It is rather larger, and does not partake much of that timidity which is so common among the pigeon family. There are several other ground doves; but our limit is reached, and we must close.

PILEOPSIS (Lamarck; *PATELLA UNGARICA*, Linnæus). This genus of molluscs is one of the many instances of Linnæan error; it was confounded with many others in the genus *Patella*, from which it may be distinguished by the shell being an oblique sharp-pointed cone, bent forward with a recurved, almost spiral summit, finely striated longitudinally, and wrinkled transversely; the aperture a round oval; the anterior margin shorter and sharper than the posterior; the base nearly round, more or less regularly crenated and indented; the anterior with a lengthened arched transverse muscular impression. In the fossil examples of this genus a testaceous deposit or support, apparently the result of successive accumulations, is visible upon the surface to which they are attached, leaving, as it were, the impression of the shell's margin. As this deposit has never been seen on the spot whence recent specimens

have been removed, it may be concluded that the animal inhabiting them seldom, if ever, removed from one spot to another. The *Pileopsis ungarica*, commonly called in this country the foolscap limpet, and its congeners, may more properly be considered to belong to the genus *Hippopsis*, according to Sowerby's opinion. There are twenty-one species not known to possess the basal accumulation observed in the fossil species. The mollusc inhabiting this genus is nearly allied to the *Patella*. It possesses two conical tentacula, and the eyes at their base; the branchia are formed in a row, under the anterior margin of the cavity, near the neck. They are found in the European seas principally, but some very large species are inhabitants of the tropical climates.

PIMELIIDÆ. A family of coleopterous insects, belonging to the section *Heteromera*, sub-section *Melasoma*, having the elytra soldered together, the wings being obsolete, the palpi filiform, or terminated by a slightly-dilated joint, and not forming a large hatchet-shaped club. These insects are of a moderate size, and generally of black or obscure colour, and of a robust form; their legs are thick and their motion slow. Many of the species are found in the sandy districts of the shores of the Mediterranean, west and southern Asia, and Africa. The genera are *Pimelia*, *Platyope*, *Diesia*, *Trachyderma*, *Cryptocheile*, *Erodius*, *Zophosis*, *Nyctelia*, *Hegeter*, *Tentyria*, *Akis*, *Elenophorus*, *Eurychora*, *Adelostoma*, *Tagenia*, *Psammotichus*, *Scaurus*, *Scotobius*, *Sepidium*, *Trachynotus*, and *Moluris*, together with numerous others recently established by M. Solier in the *Annales de la Société Entomologique de France*.

The genus *Pimelia* is distinguished by having the body of an ovoid or oval form, with the thorax narrowed, especially at the base, convex, without posterior angles, and destitute of a prorected prosternum. One of the most remarkable species is the *Pimelia coronata* from Egypt, which has the margins of the elytra furnished with a series of spines, giving it somewhat the appearance of a coronet.

PIMENTA (Lindley). A single genus, formerly the *Myrtus pimenta* of Linnæus, and still belonging to the natural order *Myrtacæ*. It is the plant which yields the common allspice, and is cultivated in the West Indies. The berries, when intended to be used as spice, should be gathered as soon as the flowers have faded, and not be allowed to ripen. They have a commingled flavour of cloves, cinnamon, and nutmegs, and hence the common name. In our stoves they grow freely in loam and heath mould, and are propagated by cuttings.

PIMPLA (Fabricius). A genus of hymenopterous insects, belonging to the family *Ichneumonidae*, and distinguished generally by the great length of the ovipositor and its lateral filaments. There are many species, some of those found in tropical climates being the largest insects of the family.

PINE APPLE is the fruit of the *Ananassa sativa* of Dr. Brown (the old *Bromelia ananas* of Linnæus), or cultivated pine apple. The culture of this celebrated fruit is one of the most important feats of modern gardening, and no branch of the business is attended with more success. In former times, if a pine plant could be fruited in three years, the gardener considered himself lucky; now, the principal crop is fruited in less than two. We have not only improved the method of growing the plant, but increased the varieties, so that they may be had at

any season of the year. It is a well-ascertained fact that there are finer pine apples grown in England than in any other country in the world. In their native countries, although the flavour may be equal, the fruit are inferior in size, and much less juicy.

The plant perpetuates itself by seed as well as by viviparous progeny. Soon after the fruit is ripe, the old plant dies, but not till it has left a successor, on the apex of the fruit, called a crown, and several suckers from the lower part of the stem. These last are mostly preferred as succession-plants, and are rooted, placed in small pots, whence they are shifted into larger and larger, until the plants attain such a size as will enable them to show and ripen off a full-sized fruit. Throughout the time of their nonage they are kept in a strong moist heat, by which their parts are greatly amplified, and in twelve or fourteen months are fit to take their final station in the fruiting-house.

PINGUICULA (Linnæus). A genus of pretty herbaceous plants, natives of Europe and North America. The flowers are diandrous, and the plants belong to the natural order *Lentibulariæ*. They are inhabitants of bogs and marshes, and known by the name of butterwort in English lists.

PINNOTHERES (Latreille). A genus of small crabs found upon our coasts, belonging to the sub-order of *Brachyurous Decapods*, and group named quadrilateral crabs by Latreille. These little crabs are found during a portion of the year, especially in the month of November, in different bivalve shells, especially in those of the muscle. The shell of the females is sub-orbicular, very slender and soft, whilst that of the males is solid, globular, and somewhat pointed in front. The legs are of moderate length, and the claws straight; the abdomen of the female is very large, and covers the entire underside of the body. They are ordinarily called pea-crabs, and it is within the shells of the molluscous animals above-mentioned that they both grow and breed. The ancients were acquainted with these little crabs, for Aristotle tells us that "there breed in some shells white and very small crabs, the greatest numbers are found in that species of muscle which have the shell protuberant; next in that of the *Pinna*, whose crab is called *Pinnotheres*. They are also found in cockles and oysters. These little animals never grow in any sensible degree, and the fishermen imagine that they are formed at the same time with the animal they inhabit." He likewise supposed that their lives were so dependent upon each other, that if the muscle loses its little crab, both shortly afterwards perish. "The pinna," according to Pliny, "is never found without its companion, which is a little shrimp, in some places a small crab, which bears it company in order to partake of its food. The pinna, gaping wide and showing her naked body to tempt the little fishes, they soon make their approaches, and, when they find they have full licence, grow so bold as to enter in and fill it; this, being seen by the guardian shrimp, by a slight rap he gives the signal to the pinna, who, therefore, shuts her shell, and suffocates whatsoever it encloses, giving a share of booty to her companion." Oppian, still more absurdly, supposed that the *Pinnotheres*, finding the shells of the bivalve open, throws a small stone between them to prevent them from closing, and so enables it to devour the inhabitant; whilst Hasselquist as ridiculously tells us, that the

crab goes out to cater for the pinna, and when it returns, cries out for the shell to be opened, which the grateful inhabitant immediately complies with. In more modern times, the people on the coasts where these crabs are found attribute to their presence the injurious qualities which some muscles possess. Say, however, has described an American species under the name of *Pinnotheres ostreum*, which is found in the common oyster of that country, and which is stated to be "excellent food; and those who eat oysters, seldom reject it when the fresh oyster is opened. In considerable numbers the crabs are often collected and served apart for the palates of the luxurious;" whence it is evident, that the opinion commonly entertained that the injurious consequences which arise occasionally from eating muscles must be owing to other causes. For some of these observations we are indebted to Mr. Thompson's valuable Memoir upon this genus, in the third volume of the *Entomological Magazine*, in which it is clearly proved that the connexion of the *Pinnotheres* is parasitic, being never found at large like some other aquatic animals which occasionally make their way into shell-fish, since, in sweeping on a bank of old muscles, "almost every shell will be found to contain one full-grown female, some two, and others three, independent of young ones; and males, which occasionally occur in common with the females, while not a single individual is to be seen." The type of the genus is the *Cancer pisum* of Linnæus. There are several other species described in the "*Malacostraca Podopthalma Britannica*," of Dr. Leach; but this author has given the young and the males as distinct species.

PINTADINA. The name given by Lamarck to one species of the genus *Avicula*, which Leach has named *Margarita*. It is the shell known as the mother-of-pearl oyster, and is described under the article *AVICULA MARGARATIFERA*, or pearl-bearing *Avicula*, and under the leading head *CONCHOLOGY*. Some mention is made of that highly-prized gem, the produce of a diseased state of the animal, and the source of an immense branch of commercial wealth and national luxury in all parts of the globe, from the very earliest period of history down to our present times. We may here offer an apology for not having fulfilled a pledge given that some account of the pearl fishery would have been furnished our readers, it having been considered unadvisable to introduce it in this division of the work.

PINUS (Linnæus). A well-known and useful genus of forest trees, belonging to the truly natural order *Coniferæ*. They are mostly natives of the mountainous parts of the northern hemisphere, and furnish the builder with the principal part of his materials. There are above forty different sorts of this genus in cultivation. Some of them are highly ornamental, and all of them are well calculated for forming sheltering screens, and for nursing trees of a less hardy nature. They are raised from seeds, and constitute a principal part of the business of British nurserymen.

PIOPHILA (Fallen; *TYROPHAGA*, Kirby). A genus of dipterous insects, belonging to the family of *Muscidæ*, and having for its type the cheese-fly, *Piophilæ casei*, an account of whose habits we have given in our second volume, p. 9. The body in this genus is small and polished; the head sub-globose, without any frontal projection, the antennæ small with a single bristle, and the legs moderately long and slender. In

our article above referred to, headed CHEESE HOPPER, or CHEESE MITE, we unintentionally confounded together two insects which are found in cheese, namely, the cheese-hopper or larva of the *Piophilæ casei*, and the cheese-mite *Acarus lactei*. We are indebted to an obliging correspondent for pointing out this mistake in the Entomological Magazine, and which we take the earliest opportunity of rectifying. The article in question is confined to the operation of the first-named insect and its transformations; with the exception of the following passage, relative to the larvæ which, feeding upon cheese, are said "to cause it to decay; the fine powder which we perceive, and which is so highly prized by the gourmand, being nothing else but the excrement of these grubs." This paragraph which, by an oversight, was introduced into our account of the larva of the *Piophilæ*, although the writer thereof had often watched the mites under a microscope, relates to them and not to the former. The anonymous writer thus proceeds, "when a cheese is infested with the hoppers there is no powder, but, on the contrary, a moisture"; now a cheese that is attacked by the mites is always powdery wherever they harbour. Any dairy-maid knows that if the cheese is not well pressed, to separate the whey entirely from the curd, it will be much more liable to the attacks of the hopper-fly than if it had been pressed as it ought to have been. They also call a cheese that is decayed by having the maggots in it, the 'wet rot,' in contradistinction to the 'dry rot,' which the mites generally, but not always, accompany. There is also a very great difference in the attacks of the two insects. The hoppers being always found in the interior of the cheese without any visible external aperture; the mites are as constant to the exterior, and never penetrate into the inside (unless there are cracks in the cheese), until the outer part where they are is entirely consumed." Entomological Magazine, vol. iii., p. 502. We are thus happy in being enabled to correct any errors into which we may unintentionally have fallen in the course of our work, deeming accuracy of far greater importance than wilful ignorance.

PIPERACEÆ. A small natural order, consisting of three genera and seventy-one species. The genera are *Saururus*, *Piper*, and *Piperoma*. In general the peppers are much more valuable in commerce than as ornaments in gardening. Their flowers are inconspicuous, and the habit and foliage afford very little variety. They are herbaceous or shrubby plants with knotted stems, and opposite or verticillate leaves. The petioles are sheathing at the base, but without stipules, and the lamina is simple, entire, and often fleshy. The inflorescence is spadix-like, the flowers bracteate, stamens definite, the anthers erect, one or two-celled, opening lengthwise, shedding smooth grains of pollen. The germen is superior and one-celled. The stigma one or more and sessile. The fruit is indehiscent, with a fleshy mesocarp, containing one or more roundish seeds.

The *Piper* and *Piperonias* are all tropical plants, abounding in the hottest parts of the East and West Indies. Their fruit are warm and even acrid spices, and the pungent aromatic principle so familiar in culinary pepper is common to the whole group. The black, the long, the cubeb, and the betel peppers, are the best known and most valuable. These, or some

one of them, are cultivated in Java, Sumatra, Borneo, and in the Phillippine Isles, and grow in the greatest abundance in Malabar, constituting one of the principal articles of export. The two sorts of pepper known as the black and white are the produce of the same plant: the black is the fruit entire, the pericarp being allowed to dry on the seed: the best white consists of the ripe seeds which have fallen from the plant, and are picked up by poor people from under the vines. The largest quantity, however, is produced by steeping the black pepper in warm water, and rubbing off the pericarps: much of the pungency, however, is thus removed, but it becomes a more slightly condiment.

The betel-pepper leaves are chewed with slices of the areca nut, as tobacco is in Europe; and, from its intoxicating powers, as well as from it allaying hunger, it is one of the most common luxuries of the East.

PISCIDIA (Linnæus). A genus of West Indian trees, belonging to *Leguminosæ*, and commonly called red Jamaica dogwood. In our collections they are rambling growing plants, often requiring to be cut down.

PISMIRE. One of the ordinary names for the ant.

PISTACIA (Linnæus). A genus of deciduous trees, natives chiefly of the south of Europe. They belong to *Terebinthaceæ*. In countries where these trees abound, the nuts are used as food, and great quantities are exported to foreign countries. The flowers are diœcious, and the male flowers are suspended over those of the female trees by the cultivators to insure a crop. The *P. lentiscus* affords the true mastic of commerce. In this country the *Pistacias* are treated as greenhouse plants, and are increased by cuttings, or by grafting to unite the two sexes.

PISUM (Linnæus). The *P. sativum* is the common pea of our gardens and fields; a leguminous genus needing no description. Field peas are usually sown in February or March; and, in order to have a succession of young pods for the table, peas are sown in every month from October to July.

PISUM. A genus of molluscs established by Megerle, now united to the genus *Cyclas*, of which it may be deemed a species.

PITCAIRNIA (Heritier). A genus of rigid spiny herbaceous perennials, bearing a spike of hexandrous flowers, and belonging to *Bromeliaceæ*. They are natives of tropical America, thrive and flower freely in light soil, and are increased by suckers.

PITCHER PLANT is the *Nepenthes distillatoria* of Linnæus, a curious herbaceous bog plant, a native of China. They are grown with great success in our damp stoves. The flowers are diœcious, and the genus belongs to *Cytineæ*.

PITTIOSPORACEÆ. A small natural order of beautiful shrubs and small trees comprising four genera, viz., *Bellardiera*, *Pittosporum*, *Bursaria*, and *Senecia*. Of these together there are twenty-two species already described. The leaves are simple and without stipules, with white or yellow flowers. The order is distinguished by the imbricate æstivation of the sepals and petals, which last, as well as the stamens, are five and seated below the germen, and by its minute embryo. The *Pittosporum lobata* is nearly hardy, and expands its sweet-scented flowers in favourable situations in the open borders.

* The impression still remains in the mind of the writer hereof, that he has seen the hoppers in cheese which exhibited no moisture.

PLACENTULA. A minute species of mollusc, considered and classed by Fichtel with his microscopic *Nautili*.

PLACOBANCHUS. A genus of naked molluscs established by Hasselt from specimens discovered in Java. It appears by his description to differ essentially from other molluscan animals; but its description requires more frequent observation of the species to enable us to assign to it a proper position in malacology. As far as we are able to judge, it appears to belong properly to the *Cyclobranchiata*, and nearly allied to the genus *Doris*.

PLACUNA (Lamarck; *ANOMIA SELLA*, Linnæus). The animal appears to be entirely undescribed of this singular mollusc; but the shell is well known to amateurs, and once bore a high price. This genus immediately precedes the genus *Anomia* in Lamarck's system, with which it was blended by Linnæus, though in form it bears but little resemblance; unlike them also in habits, it is never affixed to other bodies, and the probable organisation of the animal must likewise be perfectly distinct. The name given to this shell by Linnæus is not quite so happy as many others which have led him from their resemblance to things to adapt generic names. If that alone should guide the naturalist, this might better have been named a saddle-cloth than a saddle. It is a most remarkable mollusc, unlike every thing else in malacology, and, viewed in an anatomical light, probably presents more to astonish us than any other testaceous mollusc, were we only to consider that a shell, often six inches in diameter, encloses an animal by which it is constructed, whose utmost solidity at any part does not exceed the thickness of a sixpence, while every indication of muscular power is as strongly developed as in the gigantic inhabitant of the *Tridacna*, or other species of shells of an inferior size, such as the common oyster, whose valves cannot be torn asunder without the application of an immense mechanical force. The principal characteristic features of this singular mollusc are as above stated; the extreme thinness of the animal's body, the great delicacy of the texture of the valves which admit the rays of light to pass through them, and the strength of the hinge which presents a *point d'appui*, are scarcely to be equalled by any other mollusc. The very peculiar form of this hinge completely distinguishes this genus from all others; on one valve it may be described as resembling the letter V, the lower parts not quite joined; there are corresponding cavities on the opposite valve, so deeply indented, that they sometimes form an external projection, the substance of the shell is thin, semi-pellucid, foliaceous, and the margins fringed; its form is sometimes orbicular, and very flat, as in the *P. papyracea*, which, from its diaphanous properties, is used in Japan as a substitute for glass in their windows; the other species is generally of a squarer form, and singularly bent, as if partially folded or warped over a cylinder; the valves of both species are finely striated or wrinkled longitudinally, and the ligament attached to the powerfully-constructed hinge, the interior presents a muscular impression similar to and as large as that of the oyster. The *Placuna sellæ* presents a slight tinge of purple in the colour of its valves; but the *P. papyracea* is nearly white. There are three recent species known as inhabiting the Indian seas and the coasts and islands of Japan, which abundantly furnish the *P. papyracea*. In a fossil state they have been discovered, but they are

rare. A modern naturalist asserts, that the muscular impression of this shell is *not* remarkable; but surely he cannot have examined many specimens; we only refer our readers, who are interested in reconciling what may be termed anomalies in nature, to such examples as may daily be seen in the British Museum, in which we assert, without the fear of contradiction by any one acquainted with nature's indications of animal strength as exhibited in malacology, more strength is indicated as belonging to this feeble fragile shell than is marked in testaceous molluscs, whose habitations would bid defiance to external injury; and from their size and substance require a mechanical force incalculably greater than appear requisite for the shells of this genus; and the conclusion naturally is, that they are furnished with a closing muscular apparatus sufficiently powerful to crush their own valves, and equal to that necessary for retaining closed, or shutting the valves of molluscs incomparably thicker.

PLAGIOSTOMA (Lamarck). As no recent example of this mollusc has been discovered, Lamarck assigns to it a supposititious place in the connecting chain of malacology, and he appears to consider it an intermediate link between the genera *Lima*, *Pector*, *Spondylus*, and *Podopsis*. The shell is sub-equivalve, free, sub-auriculated, and the cardinal base straight and transverse, the apices are but little distant; the external edges of the hinge angular, straight on one side, oblique on the other, the hinge not exhibiting any teeth or serrations; there is a cardinal cavity between the apices, partly internal, opening outwards, and receiving the ligament. The animal is of course entirely unknown, and illustrates one of the numerous instances of animated beings who have totally disappeared from the face of nature, leaving the naturalists to draw analogous conclusions in support of their rank in the classification of recent objects of nature's formation. De France enumerates three species, but more have been discovered since his excellent work on Fossil Conchology.

PLANAXIS (Lamarck; *BUCCINUM SULCATUM*, Born). These are marine shells, nearly allied to the genus *Phasianella*, but the animal is entirely unknown. A distinguishing character from that genus is manifest, the *Planaxis* having the base of the columella truncated as in the *Melanopsis*, and it would have been still stronger, if, as Lamarck conjectured to be the case, they had not possessed an operculum. Shells of this genus are very small in general, transversely grooved on the exterior, of an oval conical form, solid, the aperture ovate, columella flattened, truncated at the base, and separated on the right margin by a narrow sinus or channel; the interior surface of the right margin is grooved or rayed with a callosity running beneath the summit, appearing in that respect allied to the genera *Buccinum* and *Purpura*. Sowerby, in his *Genera of Shells*, observes that he has seen one specimen with a thin horny operculum (a circumstance unknown to Lamarck), and he considers them more nearly allied to the *Buccina* and *Purpura* than to the *Phasianella*, which possess a solid calcareous operculum, and also by their having a callosity running under the summit of their right lip. Only two species appear to be known, one from India and the other from South America.

PLANORBIS (Lamarck; *HELIX*, Linnæus). Müller and Bruguière were the first naturalists who separated this mollusc from the genus *Helix* of Lin-

næus, and the propriety of so doing is manifest from an investigation of the animal constructing this shell. If no other reason existed for the separation being made, it would have been desirable in order to distinguish the terrestrial from the aquatic species, which were indiscriminately blended. This genus inhabits fresh water; the form of the shell is discoid, that is, having its spiral evolutions on a horizontal plane, or, as it were, wound round a central point, gradually increasing in size, and leaving the upper and lower sides concave and nearly similar, the spire being only but slightly elevated; the aperture is oval, dilated, and far removed from the axis of the shell; the lip is never reflected, the substance is generally thin and diaphanous, the whorls nearly cylindrical, but sometimes flattened, angular, or carinated; they possess no operculum. Lamarck does not appear to have observed in more than one species of the *Planorbis spirorbis* the very peculiar and characteristic distinction of its being heterostrophic or left-handed, commonly called a reverse shell, which also occurs in many other examples examined by the writer. This genus may be divided into two species, such as are keeled or carinated, and those not so; the *Planorbis corneus* is a specimen of the latter, and the *P. carinatus* of the former. The species of this genus inhabit the lakes and ditches of Europe. Some are known in a fossil state.

PLANTAGINEÆ. A small natural order of herbs, containing only three genera and eighty species. The species are, for the most part, mere weeds, found on waste ground all over the world. The genera are *Plantago*, *Littorella*, and *Glauz*. The leaves are stellate, and occasionally ternate; the pubescence is jointed; the flowers are brownish, and arranged in dense spikes. Their leaves are rather bitter and astringent; their seeds mucilaginous and rather acrid; those of *P. arenaria* are imported from the south of France in great quantities for the purpose of forming an infusion in which muslins are washed. *P. lanceolata* is an agricultural plant, being sown among other grasses in laying down sheep pastures, and sold by seedsmen as rib-grass. *Hort. Brit.*

The plantains have a tendency to follow the migrations of man; and have among the natives of some of our own foreign settlements been named the "Englishman's foot," for wherever it is found there our countrymen have trod. The *Littorella* is the shore-weed of British botany, and the *Glauz maritima* is the black salt-wort of the same.

PLANTANTHERA (Richards). A genus of three species of plants belonging to *Orchidaceæ*. The *P. bifolia* of Richards is the same species called *Orchis bifolia*, or butterfly orchis, of Linnæus.

PLANULACEA, in modern malacology, is the second family of the first class *Cephalophora*, first order *Cryptodibranchiata*; it includes the genera *Renulina* and *Peneroplis*.

PLANULARIA is a genus established by De France to a fossil mollusc, now united to the genus *Peneroplis*.

PLATANUS (Linnæus). A genus of highly ornamental timber-trees, natives of the Levant and of North America. Their flowers are inconspicuous and monœcious, and belong to *Amentaceæ*. The species are known by the common name of plane-trees, and both the *P. orientalis* and *occidentalis* are elegant, and, when full grown, majestic plants. They are usually propagated by cuttings planted in a shady border in autumn.

PLATINUM. This mineral was entirely unknown to the ancients, and we believe that the first known specimen came to this country about the middle of the last century. This valuable metal is usually found in grains combined with gold, iron, lead, palladium, rhodium, iridium, and osmium, and the largest mass ever discovered weighed less than twenty-eight ounces. Its main place of deposit is a vast alluvial tract in New Granada, South America. The valuable property that platinum possesses of remaining unaltered in the air, or when exposed to the action of heat at a high temperature in the furnace, peculiarly fits it for a variety of purposes in the useful arts; but the great expense attendant on its manufacture has hitherto prevented its employment for domestic purposes, if at least we except its application in ornamenting porcelain.

PLATYLOBIUM (Smith). A genus of Australian evergreen shrubs, belonging to *Leguminosæ*. From the compressed form of their pods they are vulgarly called the flat pea. They are handsome greenhouse plants, thrive well in light loam and heath mould, and are easily increased by cuttings.

PLATYPUS (Herbst). A genus of xylophagous beetles, belonging to the family *Bostrichidæ*, and distinguished by having the antennæ short, terminated by a very large club, which is destitute of joints; the body is linear, the head truncate in front, the tibiæ broad and curiously striated, and the tarsi long and very slender; the penultimate joint not being bilobed. These are curious little wood-boring insects, of which but few species are known, the type is the *P. cylindrus* of Herbst, about a quarter of an inch long, which has occurred in the New Forest in Hampshire. There are eight or nine other exotic species.

PLATYRHINUS (Clairville; *MACROCEPHALUS*, Olivier). A genus of coleopterous insects, belonging to the section *Tetramera*, and sub-section *Rhynchophora*, or weevils (see *CURCULIONIDES*), and sub-family *Anthribidæ*; the antennæ are clavate, the rostrum short and broad, the eyes entire, the body of an oblong form, and the two basal joints of the antennæ short. This genus comprises but a single British species *Curculio latirostris* of Bonndorff, which is half an inch long, and is found in *Sphæria fraxinea*, growing on the trunks of various trees. The other genera, which belong to this sub-family (which was omitted in its place) are *Anthribus*, *Rhinomacer*, *Tropideres*, *Brachytarsus*, and *Phloëobius*, all of which are British, together with a great number of genera described by Schonherr in his work in course of publication upon the *Curculionidæ*.

PLECTRANTHUS (Heritier). A genus of annuals and undershrubs natives of various parts of the globe. Their flowers are for the most part blue and didynamous, of course belonging to *Labiata*. The shrubby sorts are easily kept and propagated, but are plants of no beauty.

PLEUROBRANCHIDIUM. A naked mollusc without any trace of shell, occupying its place as a connecting link between the families *Subaplysiacea* and *Aplyniacea* in modern malacology.

PLEUROBRANCHUS (Cuvier). The shells belonging to this genus are but little known, and the *P. poranii* is perhaps the only example described. The form is large, well shaped, the edges membranous, oval, and concave beneath, convex above, the sharp edges closely united, and the summit altogether subspiral posteriorly.

PLEUROCERUS (Cuvier). The animal of this genus of mollusc is incompletely known, it appears to have a probosciform head, two lateral tentacula, subulated and pointed, the eyes externally placed at base. The shell is oval or pyramidal, the aperture oblong, the external lip thin, the internal one attached to the columella, which is smooth and twisted, without an umbilicus, it has a horny or membranous operculum.

PLEUROTOMA (Lamarck; *MUREX*, Linnæus). Shells of this genus were classed with the *Murices* by Linnæus. Bruguiere in aftertimes confounded them with the genus *Fusus*. Lamarck, in the first instance, called such of them as had a short canal *Clavatulæ*, and the others *Pleurotomæ*; but the very variable length of canal in the intermediate species induced him to class the small under the present genus, being guided only by the notch on the upper part of the edge of the aperture. With regard to the former arrangements, they cannot properly be confounded with the *Murices*, as they never possess the varices so remarkable in that genus; and from the genus *Fusus* they may readily be distinguished by possessing a long thin notch on the right side of the aperture. These molluscs are either turreted or fusiform, varying in length, terminated at the base by a straight canal more or less lengthened; the right margin with a deep narrow notch or slit near its upper part, the spiral whorls variously sculptured as in the genus *Cerithium*, between which and the genus *Turbinella* they appear to form a natural link. They possess a small horny operculum, and many fossil species are known. They inhabit the eastern and tropical seas, and many of the species are abundant in Java.

PLEUROTUMARIUM. A fossil species of mollusc established by De France, it appears intermediate with the recent genera *Turbo* and *Delphinula*.

PLICATULA (Lamarck; *SPONDYLUS*, Linnæus). The genus differs but little from the Linnæan arrangement. Lamarck has, however, separated it for the following reasons: the ligament is altogether internal as in the *Pecten*; it has the primary teeth of the *Spondylus*, but without the ears or prolonged beak which are so conspicuous in that genus. The *Placatula* also possess the faculty of affixing themselves to one another or various marine bodies grouped together in clusters, as sometimes occurs in the genus *Spondylus*; the valves are both of them closely interlocked and strongly plaited within and without; the summits are unequal and without external facets. They mostly inhabit the American seas, and several fossil species are known.

PLOIARIA (Scopoli). A curious genus of hemipterous insects, belonging to the family *Cimicidæ*, and sub-family *Reduviidæ*, having the body very long and slender, as well as the legs and antennæ, the latter being elbowed at the extremity of the long basal joint, the anterior legs are, however, short and prehensile. The *Cimex vagabundus* of Linnæus is the type of this genus, which is found in the larva and pupa state in obscure and dirty situations. In the imago state it is found in outhouses and in trees; its motion is very slow and irregular, and it balances itself like a tipula without changing its place. Its fore legs are not employed in walking, but are folded three times beneath the head, the femur resting upon the trochanter, and the tibia upon the femur, the

antennæ seeming to make up for the deficiency by being often brought into contact with the surface upon which the insect is walking. The fore legs are therefore employed as instruments for seizing the prey; the rostrum is very short and curved, and the fore legs being also short, are adapted for bringing the food to the mouth. The pupa very nearly resembles the perfect insect, but it is entirely covered with hairs scattered over the body and legs. The perfect insect is about one-fifth of an inch in length, of a whitish colour with brown spots.

PLOVER (*Charadrius*). A genus of *Echassiers*, or stilt birds, belonging to the pressirostral family, and resembling the lapwings in their haunts and their habits, but still distinct enough from them for being considered as a separate genus. The principal generic characters are as follow: the bill shorter than the head, slender, straight, compressed, and with the nasal grooves extending two-thirds of the length, which of course renders that portion of the upper mandible weak and in part flexible; the nostrils are near the base of the bill, and toward the sides pierced in, and partly covered by a membrane, which lines the grooves to a considerable extent; the tarsi are long in some of the species, and of mean length in others, and they are slender in all; the toes are three to the front, and none to the rear, united at the base by a small membrane; the first quill of the wings is shorter than the second, which is the longest in the wing.

Plovers occur in many parts of the world, indeed almost in all; and they may be considered as birds which range from place to place with the seasons, although they are not decidedly migratory. In the summer they are inland birds, dispersing in pairs for the purpose of breeding. They breed on the margins of marshes and streams, generally in wild places, but the eggs are deposited on the solid ground. In some of the species, however, the eggs are placed on the bare sand, and in others they are under cover of aquatic plants; but these differences appear to depend fully as much on the country as on the birds. After the broods are reared, the birds assemble in considerable flocks, and descend from the breeding places on the moors, first to the low grounds, and ultimately to the beach, in countries where the winter is severe. There are, however, great differences among them in these as well as in other respects. When they flock they are much esteemed as game, and the more so probably that it is very difficult to come within shot of them, as they always have sentinels when the flock is feeding, which give the alarm in a loud whistle upon the slightest appearance of danger. When the alarm is given, the whole are on the wing in an instant; and, as they fly rapidly and wheel and double adroitly with their pointed wings, they soon get out of sight. Their food consists of small ground animals, chiefly worms and mollusca; but it may reasonably be doubted whether they beat the ground with their feet, in order to bring out the worms, as is generally alleged of them. The fact is, that they are on the feeding grounds during that weather and those times of the day when the worms are out; and by the time that the worms have begun to sink deep in the ground in order to hibernate, as they do in cold and upland places, the plovers are lower down feeding upon mollusca.

The common English name plover is a corruption of the French *pluvier* or "rain bird," they being most

active when the weather is rainy or otherwise moist. Birds are instinctively good prognosticators of the weather, though of course without knowing any more of the matter than almanac-makers, and they generally utter their particular cries before the rain actually comes. In such countries as Britain, the rain very often comes about the hour of the night when the nocturnal atmosphere has made its greatest descent. The air is, however, softened, and as soon as this takes place such birds as the plovers are in motion and whistling away at the top of their bent. This circumstance led to the vulgar opinion, once very prevalent, that the plovers are the cause of the rain, which in most cases follows this unusual stir of them; whereas the fact is, that the coming rain is the cause of the greater activity among the birds. They are not the only birds which have in this way got the name of rain-birds, for the same has been said of the woodpeckers; and indeed all birds which feed upon small animals that conceal themselves in drought and come out in soft and moist atmospheres, are excited and become active before rain. Instead of bringing rain, the plovers are not, in any sense of the word, aquatic or water birds, for they never go into the water, though they do resort to the soft ground to feed; yet in their feeding they appear to give the preference to firm surfaces.

As British birds, there are three species of plover, generally understood to be resident in one part of the country or another all the year round; but they differ a good deal from each other in their habits.

THE COMMON PLOVER (*C. pluvialis*). This bird is differently coloured at different ages, and this has not only led to its being called by many names, but to the old and the young being sometimes described as different species. As a British bird it is very common in all places which suit its habits, and it is very generally distributed over other countries. It has been most frequently seen in the winter plumage, and accordingly it is usually described by the colours of that. The upper parts are blackish, spotted with golden yellow; the sides of the head, the neck, and the breast, are ash-colour clouded with yellowish-brown; the quills of the wings are black, with the ends of the shafts white; and all the under part is white. The bill is blackish, and the feet grey. The length of the full-grown bird is about ten inches and a quarter, and it is a compact bird, and, when in good condition, heavy in proportion to its lineal dimensions. Its wings are not very long, but they are firm and capable of active flight, both on a forward course and upwards and downwards. In the breeding season, the breast (of the male bird at least) becomes of an intense black; and as the bird was first noticed in this plumage, in places far to the north, it was described as a different bird from that which flocks on the low fields in autumn and the beaches in winter.

The common plover always nestles on the dry places of the upland moors, never far from the mires and pools, but not close to their margins. The nest is merely a rude channel scratched in the earth; and as both the bird and the eggs are very like the ground and the heath and lichen in colour, one may pass quite close to the nest without observing it. They make their appearance, or rather make themselves heard, upon the breeding grounds in the latter part of March, or early in April, according to the place and the season; and it is to be understood that the weather in the place which they leave, not in that to

which they come, determines their movement. In the more cold and northerly parts of Britain, where the upland forms a striking contrast to the plains by the sea and the beaches, they, as well as the lapwings, often take the hill too early. They do not of course come upon the moors while these are covered with snow or bound up in frost; but a slight return of the storm sometimes overtakes them, and though they do not tumble about on the wing, and battle with the wind and snow-flakes as the lapwings do, they are, perhaps, put to greater straits for food, as they do not dash about like the others. They appear to pine before they leave their places of winter habitation; for, although there are often many of them on the same moor, they do not appear in flocks there, even upon their arrival. It is only on rich pastures that they flock; and as they use the wing but little on the breeding-grounds, unless they are forced up by danger, each pair take up their ground, which is not invaded by any other pair. If the weather is severe they are seldom seen except early in the morning, running from the marshy pools to the cover of the withered grass and heath, in which they are soon lost to observation. If the weather is open the male very soon begins his music. It is a shrill but rather pleasant whistle, began at early dawn, and the ploughmen on the margins of the moor have their reveille in the whistle of the plover, just as those farther down have it in the song of the lark. The place for the brood is one in which exposure becomes concealment. It is not in the cover of the grass or heath, but generally in an open and rather elevated place, where one would be the least likely to look for a nest, unless well acquainted with the habits of these birds. The eggs are usually four in number, of an olive-grey colour, blotched and streaked with a dusky tint. They are large for the size of the bird, and they are arranged as those of most of the running birds are, in quatrefoil, with the small ends towards the centre. During the night the female sits closely, and the male stands sentinel at a little distance, but does not give an alarm unless danger is very pressing. When the sun beats strongly and the ground gets warm, the female steals quietly and by a circuitous route from the nest to the feeding-ground, where she continues the whole day if the sun shines unclouded, the heat of the sun being sufficient for keeping up the requisite warmth in the eggs. But if rain comes, or even a very dark cloud passes over the sun, she hurries back to her charge in the same circuitous and stealthy manner as she left it. If the feeding-ground is at some distance from the nest, the female performs the greater part of her journey on the wing; and she displays no small finesse both in rising when she departs, and in alighting when she returns. On her departure she runs crouching for a considerable distance, and then rises and flies back over the nest, and wheels and counter-marches several times before she goes off. On her return she practises the same manœuvres reversed, flying over the nest to some distance, and running to it after she has alighted. The male, though seldom seen unless when danger threatens, is always on the watch, except early in the morning and late in the evening, which are his feeding-times. He watches the female and the eggs during the night, which is rather an easy task, as there are but few enemies abroad on the plovers' ground then. In the absence of the female during the day, his watch is a little more severe, as crows are very apt to come prowling over the moors in quest of

eggs or of nestling birds. It costs the bird no small share of artifice to get rid of the crow, because the crow does not seek the bird but the nest; and where crows, whether the hooded or the carrion, are numerous, they destroy many of the eggs. From quadrupeds there is little to fear; but if a dog happens to pass, stratagems are immediately resorted to. The bird takes the wing, and alights near the dog, but always in a different direction from that in which the nest is situated. If the dog gives chase, as is always done by a strange cur upon the moor, the bird rises and flies a little way, then alights, and runs with drooping wing as if crippled. The cur is always close upon the game, but never comes up with it; and if he persevere, the sport is continued till he is drawn to a distance from the nest, and at the same time quite exhausted. Then the bird whistles loudly to his mate, announcing that all is safe; and after wheeling round and round the enemy, as if in derision, dashes back to his watch-tower.

As is the case with those of all ground birds, the young, when they break the shell, are covered with down. At first they cannot run to find their own food as the young gallinidæ do; and one can easily see the reason; the food of the gallinidæ is found in the place where the nest is, while that of the plover is always at some distance. Both parents feed them when they are in this early and helpless stage; and after they are able to run, which they are long before they can fly, both parents watch them, and entice off the enemy by manœuvres similar to those already noticed. It is generally said that the shepherds' dogs on the hill occasion no alarm to the plover, or indeed to any of the birds that nestle there.

It is generally said that the plovers moult twice in the year, the chief moult in the autumn, and a less one in the spring; and they certainly do change their colours at those times. During the great moult they are both still and silent, and are understood to hide themselves singly in the snow; and, as the ground is then beginning to be moist, worms are much more easily found than during the drought of summer. When the new plumage is complete, the birds begin to flock and to move off to their winter-quarters; and as they do this by stages, and feed well by the way, they are very fat and excellent eating.

THE DOTTEREL PLOVER (*C. morinellus*). Both the common name of this bird, and the specific one, imply that it is "a little fool," and, in those places where the birds are well known, "as stupid as a dotterel" is a character very often bestowed upon those who are not over-burdened with wisdom. The name does not apply to the bird in all its localities. When the birds flock they are an easy prey to the fowler; but when they are upon the breeding-grounds, they are not only not easily captured, but very rarely seen,—so rarely, indeed, that though analogy led to the conclusion that thousands of them must have been somewhere in the upland wilds of Britain every year, yet the birds or the eggs have been very rarely found upon the breeding-grounds, and that only of late years.

The upper parts of the dotterel are blackish-ash colour clothed with greenish, having a dull metallic gloss, and the margins and tips of the feathers reddish. The top of the head is dark grey; the streak over the eyes white; and the front and cheeks white dotted with black. The breast and flank are reddish white, with a broad band of black on the former, and

the rest of the under parts are white. The quills have black tips. The bill is black, and the feet are greenish. As is the case with the common plover, the dotterel is subject to very considerable seasonal changes of colour. As in that bird, the description usually given is that of the winter plumage after the autumnal moult; because, although the birds are seen in vast flocks in this winter dress, it is rare to get a sight even of one in the nuptial plumage, which is that by which the bird ought to be described. We believe it was first seen in this nuptial, or summer plumage, in Siberia, and, as systematic naturalists are always far more anxious to find a species than to establish a truth, it was called the Siberian plover (*C. Siberica*). In this plumage it has the front and cheeks white without black spots, the occiput black, the hind neck and sides of the neck ash colour, and the middle of the belly black. The length is nearly nine inches, and the weight, especially when the birds flock in autumn and winter, is considerable as compared with the lineal dimensions, the weight being then about five ounces.

It is probable that the greater number, if not the whole of these birds, quit Britain for warmer climates during the winter; and they make their appearance upon the low and cultivated grounds of the south of England, and the central part of Scotland, nearly at the same time, in the early part of April. They continue coming for several weeks. Their halt is not upon the very richest grounds near the sea, but rather on the cold upland ones which are nearer the moors. At that season they are in packs rather than in flocks; and these packs keep augmenting for some time; after which they gradually melt away, though some linger till nearly the beginning of June. They do this in the south as well as the north, if the place where they linger is near an extensive and dreary moor, which would lead one to suppose that they breed in all parts of the country where they can have sufficient hiding, upon the heath-clad downs in the south of England, as well as the secondary ridges of the Grampians in Scotland; but, as we have said, their manners on the breeding-grounds are everywhere so hiding, that there is great difficulty in finding them out. One may pass a cold height, half haussock and half mire, where hundreds of them may be, without the slightest chance of seeing one. The eggs are very similar to those of the plover, and arranged in the same manner, only they are considerably smaller. The appearance of the young in their early stage is very little known.

That dotterels breed not only on the southern slopes of the Grampians, but pretty generally in the Scottish mountains, is proved by the fact of their having a Gaelic name. Nor is it a little remarkable that this name should embody the same charge of folly which is implied in the common English one. It has an addition, however, which points to the places in which the nests of the birds are most likely to be found. The name is *An tàmadan mointich*, which literally means "the fool of the peat-bog." Now, these peat-bogs always lie upon the first slopes, very generally where the water parts to run different ways in the hollow between two mountains. Very generally these bogs receive a considerable supply of water even in the most dry time of the year, and they are thus in a great measure proof against the visits of man or quadrupeds. The summer is warm upon them, however, in proportion to their elevation,

and thus they abound with those small animals which serve as food for the dotterels and their broods; and, from the peculiar nature of the places, the birds breed in safety as well as secrecy. The length of the incubation, and the economy of the breeding-time generally, are not known. They return to the low country in the month of September, and then they are in numerous flocks, which keep very closely together. Even then, however, they appear upon the bleak and bare places rather than the fertile ones; the lower moors, on the secondary ridges of hills, in Scotland, and the downs and other sheep-walks in England. At this time they are very fat, and excellent eating. In Scotland they are not much attended to as game; but the case is different in England, especially in Norfolk, where they appear in great numbers, and afford sport for six weeks or two months. On these occasions they show very little fear, and do not move far from the enemy, though they keep up such a succession of rising and alighting, that it is not easy to come close up to them. One may come upon the flock on the ground close to each other; but, even if one comes near, the whole do not rise; the near ones rise, fly over the rest, and alight in front; and this may be continued to the edge of the common, or other pasture, the birds apparently taking the matter very easy, but contriving to keep at nearly the same distances. If followed to the verge, the whole rise, and traverse the common in another direction, but in the same provoking manner; and one may follow them thus for a whole day, always near, but never reaching.

They play the same sort of game with a dog, only they play it more rapidly. They let him almost into the flock, then they take the air at very low flight all round him, and he is quite at a loss to which side to turn. Thus they tease him, till he is quite worn out, by always leaping and snapping at a bird which nearly touches his nose, but of which he is never able to get hold.

Following-pieces are far more successful, as it does not appear that their instinctive resources are capable of affording them any protection against these. They fly very close, so that the most bungling marksman may make more of the value of his powder, and, by the time that he loads, they will have alighted close at hand, and be ready for another shot. A large flock on a wide down may thus be followed for a whole day, and a great number of them obtained. On foot the sport is rather fatiguing; and the best way is for two to go in concert on ponies, with assistants to pick up the birds. The gunners take the flock right and left; and when the one fires, he turns them on the other, who gets an equally good shot. This may be continued for any length of time, if the flock is sufficiently abundant, and, even if the birds attempt to make off, they may be brought back again. In November they disappear even from the south of England, and they leave Scotland sooner; but where they go, until their reappearance in the spring, is not satisfactorily known, though probably not farther than the south of Europe. In summer, dotterels are very abundant in the wild places of Russia, where they nestle and rear their broods; and when the moult is over, and all are vigorous, a retreat for the winter is made to the south-east of Europe and the south-west of Asia. The manner of their migratory flight, and the time of the day or night at which it takes place, have not been observed.

THE RING PLOVER (*C. hiatinella*). This is another British species, by no means rare, but peculiar in its localities, and thus not generally seen. It is a bank bird, frequenting the flat shores of the sea, and the barren accumulations of debris in the estuaries of the larger rivers, which places it never quits, summer or winter. It runs along the sand and gravel with much rapidity; and is an ornamental bird upon places where, with the exception of a few running birds, few living creatures are apparent. It is indeed one of the few birds that resolutely inhabit the boundary between sea and land all the year round.

The ring-plover is a small bird compared with the common plover, or even with the dotterel. The length is about seven inches, and the stretch of the wings about sixteen. The male bird, when in the summer or breeding plumage, has the upper part brownish-ash; the lower cheeks are black, passing up to the base of the upper mandible; and between the black and the ash-colour, on the crown, there is a band of white passing over the forehead and eyes; and between this white and the ash-colour, again, there is a three-cornered patch of black, with an angle directed to the front and one toward each eye; the chin is white, and the white there goes back in a point under the black almost to the nape; all the under parts are pure white; but there is a broad gorget of black on the neck, immediately above the breast, passing into a narrow black collar on the hind neck; the greater wing-coverts have white tips; and the quills, which are dusky black, have a white spot upon each, the whole forming a bar across the wing when closed; the tail is dusky brown, with the exterior feathers and the tips of the rest white, and each feather is pointed or wedge-shaped at the tip. The female has the collar less bright and defined, more white on the wings, less on the forehead, and hardly any brownish tinge in the ash-colour of the upper parts.

This is almost the only land bird which remains upon our lonely beaches in the warm season. It is its plaintive whistle that we hear as we approach the margin of the sea on a sultry day; and if we happen heedlessly to place our foot on a few eggs, almost the colour of the sand, they are the eggs of the ring-plover. There is not the least vestige of a nest, or even a hole scratched in the sand. They are on the bare surface, and on sunny days the bird leaves them the whole day over; but she sits at night, and also during the day if it rains. When surprised upon her eggs, she cannot get to a distance by stealth as the common plover does; but she turns and doubles so very quickly and so many ways, that if her very first movement is seen it is not difficult to find the eggs. Her instinct appears to be to draw attention to herself; and, while she plays off her little arts for this purpose, she utters a feeble and wailing complaint. If you follow her, she will lead you to a considerable distance from the nest, and then take the wing and fly off in a different direction; but, if you watch her, you will find that she runs to the nest as soon as she alights, though still not in one straight line.

Ring-plovers pair in May, and the young are generally hatched at the season of greatest heat, when the sand near the high-water mark is almost alive with little animals. The young run fast the instant that they come out of the shell, but they are then covered with down, and some time elapses before they get their flying feathers and are able to

take to the wing. They are, however, able to find their own food. In the pairing time each pair is solitary, and till the young are feathered and the old have moulted each bird lives solitary; but after this they assemble in little flocks, and mingle with the stronger birds of the same order, which resort to the shores in autumn and winter. Climate appears to have no effect on the colours of these birds. They are common on all beachy shores, as far to the north as Greenland; and, wherever they are found, their colours at the same season are the same.

THE KENTISH PLOVER (*C. Cantianus*). The haunts and the habits of this species, in so far as the latter are known, bear some resemblance to those of the ring-plover, and on this account the two have been confounded. Their sizes, their forms, and their colours are, however, all so different that they are as decidedly distinct species as birds can be. The Kentish plover is nearly an inch shorter than the ring-plover, and the form of its body is much more slender and elegant. The tarsi of the Kentish are longer and stouter, and the wings are proportionally shorter. The colours are also different both in the naked parts and in the plumage. The ring-plover, under all its changes of plumage, whether with age or with season, has the tarsi, the toes, and the basal half of both mandibles yellow: in the Kentish plover these are always quite black. There is no gorget and collar of black on the Kentish plover, but merely a patch on each shoulder, ragged at the margins, and not meeting each other either before or behind. The black under the eye and the white over it are both broken, and the black patch on the forehead is small and irregular, and the top of the head is rust colour. The white on the under part is still more pure, and glossed with a racy lustre on the middle of the belly. The upper part too has a reddish tinge, and not a brownish one. The colours of this bird are what may be called simple; but still it is one of those instances in which the simplicity of nature outdoes all the elaborateness of art; for all the art of the chemist cannot prepare a pigment that will come nearly up to the intense white on the under part of this bird, and no gloss of art can imitate the racy bloom upon the belly. The ring-plover is a pretty bird certainly, and it is interesting from the times and the places of its occurrence; but, in point of beauty, it is nothing to the Kentish plover.

The grounds, the numbers, and the geographical distribution of the two birds are fully as different. The ring-plover is found chiefly upon the sand; the Kentish among gravel; the one is abundant and distributed into very cold latitudes; the Kentish plover inhabits peculiar places of the warmer shores of Europe, and only where there is a run of the tide. It is not abundant any where, and in England it is very rare and very local, being met with only on some of the coasts of Kent and Sussex, more readily on the shingly beaches about Sandwich than any where else. It is the *white-fronted* plover of Meyer, and the *shore* plover of Bechstein; but, as is the case with many other birds, the continental naturalists appear to describe it in its winter plumage, in which we believe it has never been seen in England. It may migrate in the winter, though we believe it is not very usual for birds that deposit their eggs nestless on the low and warm beaches to migrate in the winter, though many, which winter on these beaches, have a northward migration in the summer. The

NAT. HIST.—VOL. III.

Kentish plover, like the ring, makes no nest, but places its eggs on a smooth dry place among the shingle. They are four in number, of smaller size than those of the ring-plover, paler cream colour in the ground, and marked with small spots and streaks of black. Little is known of the habits of these birds in the nesting time, and indeed the eggs are but seldom seen, on account of the rarity of the birds and the similarity of the eggs to many of the pebbles around them. It is probable, however, that the female follows the habit of the genus, in leaving her eggs to the heat of the sun upon clear days, and sitting in the night and during rain. The young run about as soon as they come out of the shell, and immediately find their own food, but some time elapses before they can fly. This bird agrees so perfectly with the ring-plover in the greater part of its habits that analogy would lead to the conclusion that it is a resident bird in winter, as well as in summer; and the reason of its not being observed in winter may be the absence of observers from the stormy places which it inhabits at that inclement season.

The species which we have enumerated comprise all the plovers, both general and local, that are to be met with in any part of the British islands. They form but a small fraction of the whole genus, of which, as we have said, there are species in every part of the world. The manners of the whole are so much alike, however, that very brief notices of a few of the others will suffice. Africa is a great plovers' country, from the dryness of the surface at one period of the year, and the heavy rains at another.

CROWNED PLOVER (*C. coronatus*). This is a South African species, and among the largest birds in the whole genus. It measures a foot in length. The upper plumage of the body is greenish-brown; the top of the head black, surrounded by a circle o. white; the chin is black, and so are the quills; and the greater coverts of the wings are white, and the tail-feathers whitish, crossed by bars of black; the front of the neck is grey, and the breast russet, waved with greenish and dotted with black; the bill and feet are reddish.

This species belongs to a sort of subgenus, the chief part African, which differ considerably from the characteristic plovers, whether we take the type of the common plover as shifting its abode with the seasons, or that of the ring-plover as remaining on the same ground all the year round. The members of this group, instead of having the scales on the tarsi more or less reticulated, as they are in the typical plovers, have them escutcheoned in a manner approaching those on the gallinaceous birds. Their colours are also much more broken than those of the typical plovers. They are found through the whole length of Africa, from the Cape of Good Hope to Egypt. This difference in the character of the feet, and also in the colour, indicates a difference of habit, a less aquatic one than that of the true plovers, though they never go into the water beyond the naked part of the legs; but the precise nature of this difference is not known, as the habits of these birds have not been studied with any thing like attention. We shall just name one or two of the others which have these characters.

BLACK-HEADED PLOVER (*C. melanocephalus*).—This species occurs in Egypt and also in the central parts of Africa. It measures eight inches in length. The upper part is blackish, and so is the eye-streak,

H H

which is very broad, and the top of the head. A narrow streak above the eye, the front of the neck, and the breast, are very pale russet. The coverts of the wings are whitish ash, and the quills mottled black and white. The tail-feathers are bluish, with the tips of the external ones black and white. All the under part from the breast is white. The bill is blackish, and the feet bluish. In the breeding season the male acquires a black gorget, but loses it when that season is over.

SPUR-WINGED PLOVER (*C. spinosus*). This species is African, and about eleven inches in length. As the specific name imports, the turn of the wing is armed with a horny spur. The upper plumage is reddish brown. The head greenish black, and furnished with long thread-like feathers. The throat, breast, quills, and tips of the tail-feathers are black. The sides of the neck, the larger coverts of the wings, and the belly, are yellowish white. The spur is whitish, and the bill and feet black. The neck of the female is whitish.

HOODED PLOVER (*C. pileatus*). This is also an African species, measuring about ten inches in length. The upper parts are reddish grey, the head dark, and a band down each side of the neck; the chin also has a black band passing round the throat; the nape is white, the quills and tips of the tail-feathers are blackish; all the under parts are white, sometimes streaked with dusky on the foreneck and breast; the bill, and a naked membrane in front of the eye-brow, are yellow; the feet are red.

Those of this peculiar type are not exclusively confined to Africa; there are some in South America, one of which is the

CAYENNE PLOVER (*C. Cayanus*). Although this one is named the Cayenne plover, it is more of a Brazilian bird, Brazil being much more a ploverian country than Cayenne. It is a bird about nine inches long; the upper part is blackish, mottled with grey and white on the mantle. There is a broad band of black in front of the eyes, and a breast-plate of the same; a large patch of grey, margined with white, covers the occiput; the tail-feathers are white with black tips; there are red spurs to the wing; the bill is black, and the feet orange; it will be perceived that, except in size and colour, this bird bears a strong resemblance to the spur-winged plover of Africa. Specimens of this group also occur in Asia, one of which is the

WATTLED PLOVER (*C. bilobatus*), which is a native of India, and measures about ten inches in length. The upper plumage is yellowish grey; the top of the head black; there is a white spot behind the eye; a white band across the coverts of the wings, the quills black, the lateral tail-feathers white, and a black bar across the others; the bill and feet are yellow, and there is a painted wattle or membrane of the same colour pendent from each angle of the gape.

There are other plovers of Africa which have not the characters of the group which we have been noticing, and they are generally of a smaller size. Among them we may mention the

DOUBLE-COLLARED PLOVER (*C. bitorquatus*). It is about seven inches in length, the same size as our collared plover, but rather a more showy bird. The upper parts are brown, glossed with metallic reflections; a white band passes over the forehead, the eyes, and the nape; the neck is grey, with a black collar, then a white, and below that another black

one, extending partly on the breast; the outer tail-feathers and all the under parts are white.

There are various species of plovers in Australia, which are generally of rather small dimensions, and appear in their habits to follow the ring-plover rather than the common plover.

RED-CAPPED PLOVER (*C. pyrocephalus*). This is seven inches long. The upper parts are brownish grey; the top of the head bright brownish red, with a band of white on the forehead; the lower coverts are brown with white shafts, and the middle ones are mottled with grey and white; there is a half collar of red on the neck, and a gorget of black on the breast, and the space between these, and also all the under parts, are white; the bill is black and the feet reddish.

The islands of the Eastern Archipelago, and near the remote isles of the Pacific, have their plovers, but they do not appear to differ from the other plovers of warm countries in any essential point.

America, north, south, and central, contains a great number of plovers; those of the north bearing a very considerable resemblance to the ones with which we are acquainted in Europe. The common plover of Europe, which is indeed a plover of many parts of the world, is by no means rare in North America; but as its appearance and manners are nearly the same every where, to repeat either would only be occupying space without any corresponding advantage. It seems, however, that this species is considerably more migratory in America than it is in Europe, just as it is more migratory in continental Europe than in the British Islands. But this might be expected, because all birds are more migratory in North America than they are in the corresponding latitudes of Europe. The mountains there are not well adapted for being the summer retreat of birds, especially stilt birds, which, though they are never in the water, always like to be near it, and therefore the summer migration, which is an upland migration with us, and may be north, south, east, or west, according to circumstances, is a latitudinal migration in America, always to the north; and the greater number of the stilt birds which make their appearance in the United States during the winter, pass the summer northward of the St. Lawrence and the great lakes, where the marshy country, and the dry and warm season, are remarkably well adapted to their habits. Those plovers, which may be said to be properly American birds, are not quite so migratory, though they also shift their ground a little with the seasons. We shall notice a few of them.

WILSON'S PLOVER (*C. Wilsonius*). According to Wilson, by whom it was first observed, "This bird very much resembles the ring-plover, except in the length and colour of the bill, its size, and in wanting the yellow eyelids. The males and females of this species differ in their markings, but the ring-plovers nearly agree. We conversed with some sportsmen near Cape May, who asserted that they were acquainted with these birds, and that they sometimes made their appearance in flocks of considerable numbers, others had no knowledge of them. That the species is rare we were well convinced, as we have diligently explored the shore of a considerable part of Cape May, in the vicinity of Great Egg Harbour, many times at different seasons, and had never seen them before. How long they remain on our coast, and where they winter, we are unable to say. From the circumstance

of the oviduct of the female being enlarged, and containing an egg half grown, apparently within a week of being ready for exclusion, we conclude that they breed there. Their favourite places of resort appear to be the dry sand-flats on the sea shore. They utter an agreeable pipe note. This species is seven inches and three-quarters in length, and fifteen and a half in extent; the bill is black, stout, and an inch long, the upper mandible projecting considerably over the lower; front, white, passing on each side to the mandible; the eye is bounded by a band of black of equal breadth; lorics, black; eyelids, white; eye, long, large, and dark; from the middle of the eye backwards the stripe of white becomes duller, and extends for half an inch; the crown, hind head, and auriculars, are drab olive; the chin, throat, and sides of the neck, for an inch, pure white, passing quite round the neck, and narrowing to a point behind; the upper breast below this is marked with a broad band of jet black; the rest of the lower parts, pure white; upper parts pale olive drab; along the edges of the auriculars and hind head, the plumage, where it joins the white, is stained with raw terra sienna; all the plumage is darkest in the centre; the tertials are fully longer than the primaries, the latter brownish black, the shafts and edges of some of the middle ones white; secondaries and greater coverts, slightly tipped with white; the legs are of a pale flesh-colour; toes bordered with a narrow edge; claws and ends of the toes, black; the tail is even, a very little longer than the wings, and of a blackish olive colour, with the exception of the two exterior feathers, which are whitish, but generally the two middle ones only are seen. The female differs in having no black on the forehead, lorics, or breast, those parts being pale olive."

THE KILDEER PLOVER (*C. vociferus*), is a very common species in North America, and makes itself known by its cry, which resembles the sound of the name popularly given to it. In the depth of winter, when the ground is covered with snow, it resorts to the sea-shore, where, indeed, it is found at all seasons of the year. No sooner, however, have the rivers broken up, than its shrill pipe is again heard, sometimes roaming to considerable distances from its favourite localities, at others skimming the surface of the sea coast, or exploring the watery flats and meadows on foot. The newly-ploughed fields, bare flats which contain shallow pools, dry sandy fields near the sea shore, are its favourite haunts on the advance of spring; and about the beginning of May it chooses to breed in some of these latter situations. It is not over particular in the construction of its nest. It is a mere hollow, lined with any materials as are most conveniently come at, such as bits of sticks, straw, pebbles, or earth. Indeed, in some instances, it has been found to dispense with a nest altogether, and to bring forth its progeny on the bare ground. The eggs are generally four in number. They are of a yellowish clay or vivid cream colour, thickly dotted over with spots of black. Their size is uncommonly large in proportion to the size of the bird, measuring fully an inch and a half in length, and rather more than an inch in breadth. They taper to a narrow point at one extremity. During the breeding season they exhibit much anxiety and alarm for the safety of their progeny. At this season they may be seen now floating about, high in air, now approaching the surface of the earth, then skimming the surface of the

ground, then limping about on one foot as if they were lame, the while uttering the most clamorous, piteous, and incessant cries of *Kildeer, Kildeer*. The instant a person approaches, his ears are assailed with a continuous strain of this harassing noise, and, if his object seems to be to search out the nest, the birds flutter about near to his person, continuing this annoyance till he is generally obliged to abandon his search. On these occasions they betray much cunning in never alighting near the particular spot where the nest is placed. In the spring and fall of the year, these cries are often heard in the night, more especially in moonlight nights; and, from the circumstance of their flying abroad in the dark, it is probable that they see better at these times than most of their tribe. Worms are understood to be their principal food; and, as there is a species of these which rise to the surface of the ground during the night, it is extremely likely that this is their principal inducement to be abroad at this season.

The Kildeer is much more common in the southern states in winter than in summer. In South Carolina they are very numerous in the months of February and March, in the rice-fields, and not unfrequently around the planter's yards, where the negroes frequently amuse themselves in catching them with a line, having a crooked pin baited with a worm attached to the end of it. Their flight resembles that of the tern, but it is more powerful; and they often soar aloft to a great elevation in the air. They have a semi-aquatic habit, and are very fond of walking in shallow pools of water, and also of bathing themselves in the summer months. They are strong and vigorous in the wings, and can run with astonishing rapidity. In this exercise, as well as in walking or standing, they carry the body in a stiff horizontal position, which gives them the appearance of a well-drilled recruit standing at attention. Their flesh is not generally considered as very delicious food; but in autumn, when the birds become fat, it is not at all contemptible.

In the drought of summer these birds frequent the channels of brooks and small streams, where they feed upon small aquatic insects. They resort to the sea-shore at the beginning of autumn in small companies, seldom more than ten or a dozen being observed in one flock. They then become more silent, and also more difficult to be approached.

Its size is ten inches long, and about twenty inches in the stretch of the wings. The bill is black; the frontlet, chin, and the ring round the eye, are white; the front of the crown and the auriculars, from the bill backwards, are blackish olive; the eyelids are bright scarlet; the eye is very large and of a deep black; from the middle of the eye backwards, there is a stripe of white; there is a broad band of black round the lower part of the neck, and under that there is a band of white, followed by another rounding band or crescent of a black colour; the rest of the lower parts are pure white; the crown and hind head are light olive-brown; and the back, scapulars, and wing-coverts, are of the same colours, skirted with brownish-yellow; the primary quills are black, streaked across the middle with white; the rump and tail-coverts orange; the tail is of a tapering form, and of a dull orange colour, crossed near the end with a broad bar of black, and tipped with orange; the two middle feathers nearly an inch longer than the adjoining ones; the legs and feet are of a pale

light clay colour. The tertials, as is usual in this tribe, are very long, reaching nearly to the tips of the primaries. The exterior toe is joined by a membrane to the middle one, as far as the first joint.

BLACK-BELLIED PLOVER (*C. apricurius*). This species is, in some of its characters, intermediate between the plovers and the lapwings, but still its habits are more those of a plover. It is rather a large bird. It is twelve inches long, and twenty-four in the stretch of the wings. The bill is an inch and a quarter in length, of a black colour, thick, and deeply grooved on the upper mandible; the head and globe of the eye are uncommonly large, the latter is of a deep bluish black colour; the front is white; the top of the head and the hind head are black, spotted with golden yellow; the back and scapulars are dusky, sprinkled with similar golden orange spots, mixed with other spots of white; the breast, belly, and vent, are black, and the sides of the former are whitish; the wing-quills are black, and the middle of the shafts white; the greater wing-coverts are black, tipped with white; the lining of the wings are black; the tail is alternately barred with blackish and pure white; the tail-coverts are pure white; and the legs and feet are of dull lead colour. The outer toe is joined to the middle one by a broad membrane; the hind toe is uncommonly small.

These birds require a considerable length of time to acquire their colours, and consequently they are found in various states of plumage. At first the breast and belly are white, but this colour gradually appears mottled with black, until latterly the bird assumes an entirely black colour. The spots of orange or golden on the crown, hind head, and back are white at first. In every stage of the plumage the species is distinguished by the large size of the head and the thickness of the bill.

It is most frequently met with in the mountains of Pennsylvania late in April, frequents the countries towards the mountains, and seems uncommonly fond of the newly-ploughed fields, where it constructs its nest of the most simple materials slightly woven together. The eggs are four in number, of a bright olive colour, sprinkled with black, and are uncommonly large for the size of the bird. They have often two broods in the same season. They are very clamorous during the breeding season, and exceedingly shy and watchful. Winged insects, worms, grubs, and different kinds of berries, of which latter, the species called the dew-berry, they are particularly fond. They resort to the sea-coast, taking their young with them, where they are joined by vast multitudes just returned from their breeding places in the north. They remain about the sea-shore until the beginning of November, when they take their departure for the south.

There are a good many more species of plovers in various parts of the world, and it is probable that there are not a few hitherto undiscovered. It is not necessary, however, to notice any more, as the species of which we have given the outline reach all the varieties of character that are to be met with in the genus.

PLUM is the *Prunus domestica* of Linnæus, a domesticated fruit-tree, of which there are many varieties. They belong to the natural order *Rosaceæ*, and in no other instance has the effects of cultivation been more conspicuously exemplified than in the improvement of the wild sloe of our woods and hedges.

In the wild state the fruit are small and austere; in their cultivated condition they appear as the luscious green gage, and as the ample magnum bonum, with numberless varieties more or less approaching these in quality and size. The different sorts are propagated by grafting or budding on the common plum stock raised from seeds, or the Brussels plum stock.

PLUMBAGINEÆ. A small natural order comprising three genera, viz., *Statice*, *Armeria*, and *Plumbago*, and of these genera there are eighty-two species. They are low shrubs or herbaceous plants with showy red or blue flowers. All the *Statice*s and *Armeria*s are well worth cultivation, as they enrich every floral collection in which they have a place. The different species of *Plumbago* are remarkable for the acidity of their juices. The thrift (*Armeria*), and the sea lavender (*Statice*), are like the plumbagines very ornamental plants, but they differ greatly from them in their properties. They are bitter, tonic, and astringent. *Statice Carolinaria* is said to be one of the most powerful astringents known. The root is the part employed, and is much used by some medical men in America. *Plumbago Capensis* is a handsome free-flowering greenhouse plant, and thrives in any rich soil; the *Statice*s are mostly hardy plants, and succeed in the open ground.

PLUMIERA (Linnæus). A genus of evergreen trees and shrubs, chiefly natives of South America. The flowers are pentandrous, and the genus belongs to *Apocynææ*. The species are fine ornamental stove plants, thriving in any light porous soil. They require to be kept dry when not growing freely, which causes them to flower abundantly.

PNEUMODERMA. A naked molluscous animal, described by Péron in Freycinet's expedition to Australia; only one species is known, and it is classed between the genera *Clio* and *Phylliroe*.

PNEUMORA (Thunberg). A genus of orthopterous insects, belonging to the section *Sallatoria*, and family *Locustidæ*, having the legs much shorter than the body and slender, the thorax small and bipartite, the abdomen very large, and bladder-like; whence the name of the genus, which signifies air. The species are few in number, of moderately large size, and confined to Southern Africa, where they are found on different plants in September and October.

POA (Linnæus). A genus of useful agricultural plants, and of which our finest pastures are formed. They are chiefly natives of the northern hemisphere, and with other grasses clothe the hills as well as the valleys of every temperate climate. Thirteen species are found in Britain.

PODALYRIA (Lambert). A genus of handsome conservatory or greenhouse plants, natives of the Cape of Good Hope, belonging to *Leguminosæ*. Although named after Podalirius, one of the mythological sons of Æsculapius, none of the species are medicinal. They are propagated by cuttings.

PODANTHES (Haworth). A genus of undershrubs, natives of the Cape of Good Hope, bearing pentandrous flowers, and belonging to the natural order *Asclepiadææ*. This genus is nearly allied to *Stapelia*, and required to be kept in dry porous soil, and cautiously watered.

PODOCARPUS (Heritier). A genus of evergreen trees, mostly natives of south-eastern Asia. The flowers are monœcious, and the genus belongs to *Coniferaæ*. Several species of this genus have been

introduced into our greenhouse collections, where they thrive in a mixture of loam and moor-earth, and may be increased by cuttings. The Chinese species are pretty hardy, and promise to be acclimated so as to stand in our shrubberies.

PODOPHYLLACEÆ. A small natural order of plants, consisting of two genera, viz., *Podophyllum* and *Jeffersonia*, of each a single species. They are erect plants, growing in damp shady places, with stamens twice as many as the petals; the ovary single, the stigma thick and sub-peltate, and the seeds indefinite. The genera are North American plants. Their roots are said to be cathartic, their herbage narcotic and poisonous, and their fruit eatable, but far from pleasant. *Podophyllum peltatum* is the wild lemon or may-apple of the colonists, and its root, whether in decoction or powder, is a valuable aperient, being one of the most safe, easy, and certain known. The plants are increased by division.

PODURIDÆ (Leach). A family of apterous insects, belonging to the order *Thysanura*, Leach; the head is distinct from the thorax, bearing two filiform antennæ composed of four simple joints, or with the last of these joints articulated, the parts of the mouth small, mandibulated, the legs six in number, and the abdomen terminated beneath by a forked appendage, applied, when at rest, along the underside of the body, and serving for leaping. These insects are of small size, they are very active in their movements, and are generally found in damp situations under stones, decayed leaves, &c., or beneath the bark of trees. Other species are found upon the surface of standing water, where they are, nevertheless, enabled to execute their leaps. They are sometimes found upon the snow, and occasionally they assemble together in considerable numbers, looking like a small heap of gunpowder when seen at a little distance; when alarmed, however, the entire mass skips off, and soon entirely disappears. It is probable that they feed upon decaying vegetable matter.

These insects are oviparous, and undergo no metamorphoses, quitting the egg under the shape which they retain through life, they grow rapidly, and change their skins. De Geer observed some of them in Holland in a living state, at the time of the greatest cold, their eggs being near them, the latter were of a yellow colour, which became dark red when they were nearly ready to hatch. The young ones, when first hatched, carry their tails stretched out behind. The aquatic species were also observed by him to be able to survive their removal from the water but a very short time; whence it is most probable that the aquatic species are different from those found upon land. About twenty species have been described as belonging to the genus *Podura*, including the *Podura plumbea*, Linnæus, of a leaden colour, found under stones, but never met with in society; *Podura aquatica*, Linnæus, found in quantities upon standing waters; *P. nivalis*, found upon snow and in woods.

The genus *Smythurus* comprises those species which are of a globular form, and have the terminal joint of the antennæ annulated. The type is the *Smythurus fuscus*, Latreille, found in moist woods.

Mr. Templeton has published a valuable Monograph upon the Irish species of this family in the second number of the Transactions of the Entomological Society.

PCECILUS (Bonelli). A handsome genus of coleopterous insects, belonging to the section *Pen-*

tamera, family *Carabidæ*, and sub-family *Harpalides*; the body is of an oblong and depressed form, the wings sometimes short, the thorax narrow at the base, the labrum short, truncated mandibles; with small teeth at the base, third and fourth joints of maxillary palpi of equal length. These are very active insects, which make their appearance in the early sunshiny days of spring and summer, when they may be seen running with great quickness about footpaths. The type is the *Carabus cupreus*, Linnæus, a very abundant species, of a fine coppery-green colour; there are several other British species.

POINCIANA (Linnæus). A genus of beautiful East and West Indian shrubs, or small trees, belonging to *Leguminosæ*. It is called by the colonists Barbadoes flower-fence, and is a highly ornamental plant as well in foliage as in flower. They require the strong heat of a stove to flower well, and may be raised from cuttings or from imported seeds.

POISON OAK is the *Rhus toxicodendron* of Linnæus, a hardy trailing plant, long ago introduced into our gardens.

POIVREA (Commelin). A genus of herbs and climbers, bearing fine flowers, and belonging to *Combretaceæ*. The species of this genus was formerly considered *Combretums*, but it now forms a section of that genus, distinguished by having ten stamens and five angular seeds. Most of them strike root by cuttings; but some of them are so difficult to root, that they can only be propagated by root grafting.

POLANISIA (Raffles). A genus of pretty annual plants, mostly natives of India. Their flowers are dodecandrous, and the genus is ranged among the *Capparidaceæ*.

POLISTES (Latreille). An extensive genus of exotic hymenopterous insects, belonging to the family of the social wasps (*Vespidæ*), and distinguished from the typical wasps by the more slender form of the body, the basal segment of the abdomen being smaller and narrower than the second, the wings are longitudinally folded, the eyes internally emarginate or kidney-shaped, and the portion of the internal margin of the terminal part of the mandibles is shorter than the basal part, with the clypeus toothed in the middle.

The habits of these wasps are in many respects similar to those of the genus *Vespa*, or true wasps. Like them they reside together in vast societies, composed of males, females, and neuters, in nests of variable size, containing hexagonal cells. Some of the exotic species construct these nests of a very strong material resembling pasteboard, which they also defend by a common envelope. Others, comprising the European species, form their nests of a more papyraceous substance; and *P. gallica*, which is common in France, builds its nests on the branches of shrubs, which somewhat resemble a small bouquet or rose, and consist of not more than twenty or thirty cells, which are arranged in a single tier. In some of the species, however, the cells are of a surprising number, and arranged in successive layers supported by pillars. It is in the spring that the foundation of these nests are commenced by the female, which was impregnated in the preceding autumn. The eggs at first deposited are destined only to produce neuters, which assist her in her labours; but towards the summer she deposits eggs which will bring forth males and females. At this period several of the cells are found to be filled with pure honey.

It is a peculiarity in the nests of the European *Polistes* that the cells are not arranged horizontally, but vertically, which is probably owing to the circumstance, that, as there is no outward covering to the nest, the rain would lodge in the cells if they were placed in an upright position, whereas, when arranged vertically, the rain falls off without resting. The following is a figure of the nest of *Polistes Gallica*, a species somewhat smaller than the common wasp, and of the same colours, and which is interesting on account of its being the species attacked by the *Xenos Rossi* of Kirby.

Some of the species having the second joint of the abdomen very large, the preceding forming a clavate peduncle, have been separated into the genus *Epipone*. The *Vespa tatra* and *midulans* of Fabricius belong to this genus, the latter of which with its nest and parasite, belonging to the genus *Chalcis*, is figured by Reaumur in the sixth volume of his *Memoirs*. The nests of these species are very large, and are suspended in trees, the exterior of the nest being composed of the most beautiful paper-like material, over which from its fine polish the rain glides without doing the least damage. The study of the exotic species of these genera requires much attention, and has hitherto been greatly neglected.

POLLICIPEDE (Leach). A genus of molluscs, constituted by the late Dr. Leach, but now considered only a species of the genus *Pentalepas*.

POLYERGUS (Latreille). A genus of ants. See **FORMICIDÆ**.

POLYGALA (Tournefort). A genus of handsome evergreen shrubs, all from the south of Africa, of perennial herbs, natives of Europe, and a good many annuals from North America. The flowers are diadelphous, and the genus belongs to the order to which it gives a title, viz.

POLYGALACEÆ. A natural order of plants, consisting of six genera and sixty-four species. The genera are *Polygala*, *Muraltia*, *Mundia*, *Securidaca*, *Krameria*, and *Monina*. Most of this order are interesting to the lover of plants, as well for the neatness of their foliage as for their handsome flowers. The *Polygalæ* are remarkable for the union of their stamens into a single body, their one-celled anthers opening with a pore and their irregular petals, one of which is often keel-shaped, and beautifully bearded. The leaves have generally a bitter astringent taste, and the European species are stomachic and stimulant, and are supposed to possess an influence over the lacteal secretion of cattle fed upon them; hence they have received the name of milkwort. Several of

them are useful medicines; while one, the *P. venenata*, a native of Java, is remarkable for the poisonous qualities attributed to its leaves, which, if only touched, produce violent sneezing and oppressive faintness. *Monina polystachya*, is the yal-hoe of Peru, where it is used as a cure for dysentery. *Krameria* deviates more than any other genus in this very natural group from the normal structure of its associates; its sepals are generally four, rarely five; the stamens four or three, and single, or but slightly connate by their filaments. *K. triandra* is the rhatany, which is a valuable astringent tonic. The whole are propagated by cuttings or seeds.

POLYGONACEÆ. A natural order comprising fourteen genera and above one hundred and eighty-eight species. The knot-wort, the rhubarb, the sorrel and the dock, which, with other associated genera, form this type, are herbaceous, rarely shrubby plants or trees, with knotted stems and branches, simple alternate leaves, revolute in veneration, dilated sheathing petioles, and acreate stipules. The flowers are in general united, sometimes separated, and either solitary or disposed in fascicles or racemes. The perianth is free, regular, persistent, without sepals, often coloured with a three to six parted limb. The stamens are definite, exerted from a torus, lining the bottom of the calyx; the filaments are free, the anthers two-celled, opening lengthwise; the germen is superior, one-celled, and contains a solitary ovule; the styles are from two to three, and the stigmas simple or feathery. The fruit is dry and indehiscent, bladder or nut-like, and often covered by the persistent calyx.

Along with many of the most common weeds which cover waste ground in every latitude, there will be found in this type several important officinal and dietetic plants, the chief of which are the rhubarbs, the sorrel, and the buck-wheat.

The genera in this order are *Cuccoloba*, *Polygonum*, *Oxyria*, *Brassicella*, *Tragopyrum*, *Atropharia*, *Rumex*, *Emex*, *Podopterus*, *Triplaris*, *Rheum*, *Calligonum*, *Eriogonum*, and *Kœnigia*.

POLYLEPAS (Cuvier). A genus of molluscs, belonging to the family *Lepidææ*, one species of which constitutes Dr. Leach's genus *Scalpellum*.

POLYOMMATUS (Latreille). A genus of butterflies, comprising the pretty little blue species so common in our fields, and belonging to the family *LYCENIDÆ* (which see). This is a very extensive genus, distinguished by having the posterior wings destitute of a tail or produced anal angle. The British species are termed blues, from the elegant shades of that colour with which the upper side of the wings are ornamented, whilst the beautiful eye-like spots on the under side of the wings have given rise to the generic name, which is derived from the Greek, and signifies "many eyed." The larvæ feed upon various kinds of grasses. These pretty little butterflies are amongst the objects which do not fail to attract the attention of the most inquisitive in a summer day's stroll. "We have few more jealous and pugnacious insects," says Mr. Knapp, "than the little elegant blue argus butterfly (*P. alexis*, Stephens), noted and admired by all. When fully animated, it will not suffer any of its tribe to cross its path, or approach the flower on which it sits, with impunity; even the large admirable (*Vanessa atalanta*) at these times it will assail and drive away. There is another small butterfly, the copper (*Lycæna phléas*, Fabricius), however, as handsome, and perhaps still

more quarrelsome, frequenting, too, the same station and flowers; and a constant warfare exists between them. We shall see these diminutive creatures, whenever they come near each other, dart into action, and continue buffeting one another about till one retires from the contest, when the victor returns in triumph to the station he had left. Should the enemy again advance, the combat is renewed; but, should a cloud obscure the sun, or a breeze chill the air, their ardour becomes abated, and contention ceases. The pugnacious disposition of the argus butterfly soon deprives it of much of its beauty; and, unless captured soon after its birth, we find the margins of its wings torn and jagged, the elegant blue plumage rubbed from the wings, and the creature become dark and shabby."—*Journ. of a Nat.*, p. 277.

There are about fifteen British species, including the azure blue (*P. argiolus*), relative to which a long controversy has been maintained in natural history, on the question, whether it is a double or single-brooded species; the small blue (*P. albus*); and the mazarine blue (*P. acis*), which seem to belong to a distinct subgenus established by Dr. Horsfield in the Lepidoptera Javanica under the name of *Pithecopus*. The others, including the large blue (*P. Arion*), figured in our plate of British butterflies; the chalk-hill blue (*P. Corydon*); the Adonis (*P. Adonis*); the common blue (*P. Alexis*); and others, are true *Polymnati*.

POLYPUS. Under this head we shall introduce some interesting matter descriptive of a class of animated nature which, take it altogether, may be considered as the most wonderful of created beings, proving, beyond all argument to the contrary, the opinion every enlightened naturalist must subscribe to, that no matter how inferior in the scale of nature animals may be, they, nevertheless, have functions to perform as important as those of the mightiest structure; and another convincing proof to the reflective mind, that, in proportion to the tenacity of life enjoyed by these animals, and their reproductive powers, in the same ratio their usefulness must be appreciated, though it cannot always be fathomed by finite wisdom. We propose, with this opportunity, to introduce some account of the *Polypi* "peopling the vast empire of the deep," those wonder-working stone-masons, whose incessant industry raises mountains from ocean's profound abyss, forming what are commonly termed coral rocks and reefs, so remarkable in the south seas and other parts of the world. We shall, in the first place, separate the fresh-water *Polypi* from those which we intend calling the coralliferous *Polypi*, that is, the animals constructing barriers that defy the tempest's devastating shocks in the midst of ocean's empire, forming immense islands destined to fall under the controul of man, and to afford him an opportunity of exercising his superior intellect, in bending all things created to his necessity or convenience under the divine will of his inscrutable Maker. We will commence with the fresh-water *Polypi*. Most of the observations are the result of an able naturalist's long study—many we can personally confirm—and the others we fully rely upon, though they are so marvellous as to excite scepticism in persons altogether unused to investigate nature's mysterious operations.

Polypi, whether marine or fluviatile, are gelatinous animals, consisting of a long tubular body, fixed at the base, and surrounded at the mouth by arms or

tentacula. They are many of them inhabitants of the fresh waters, and are among the most wonderful productions of nature. The particulars of their life, their modes of propagation and powers of reproduction, after being cut to pieces, are truly astonishing, and baffle the efforts of reason to account for. Nor was it till after repeated experiments by eminent naturalists that the scepticism of the philosophic world was overcome. The green polypus, a species that will fully illustrate the nature of the whole tribe, is found in clear water, and may be seen in great numbers in small ditches and trenches of fields generally in the months of April and May. It attaches its body to the under parts of leaves, and to the vegetables growing beneath the water. The long tubular body has its head furnished with eight, and sometimes ten, long feelers or tentacula, surrounding the mouth. It possesses the faculty of contracting its body very suddenly when disturbed, appearing like a round green spot; but the danger past, it resumes its usual position.

It is of a very predaceous nature, and feeds on the various species of small worms or aquatic insects that unguardedly approach it, when they are instantly seized by the polypus, conveyed by its arms into the mouth, and gradually swallowed as a snake gorges a frog. It is capable of swallowing worms thrice its own size, from the dilatibility of its body. Two of these animals have been seen attacking the same worm by opposite extremities, each gradually swallowing its respective portion, till, their two heads coming in contact, the larger one has gorged not only the worm, but the polypus at the opposite end; and, what is more wonderful, the animal thus engulfed, after remaining a considerable time so confined, has been ejected unhurt with the long-contested prize, which he then remained the undisturbed possessor of. The remains of animals upon which they feed are evacuated by the mouth, that being the only aperture to their body. The multiplication of the species is by a process nearly resembling vegetation. The young are seen emerging from the parent's sides, one or two at a time, and sometimes more; and these young are frequently again prolific before they drop off. Thus it is no uncommon circumstance to see two or three generations at one time on the parent polypus.

The most marvellous, but, nevertheless, true circumstance respecting these extraordinary animals, is their tenacity of life and power of reproduction.

It appears almost impossible to destroy their existence. Mr. Trembley, of Geneva, records numerous experiments made by him. He relates, that, when they are cut into small pieces, each portion produces its own head and tentacula, springing into life again, and multiplied almost to an endless extent, by such dissection upon each of them, it became a perfect animal. Even when turned inside out it suffers no material injury, shortly after taking its usual food, and resuming all its other functions.

The above brief view of the fluviatile, or fresh water polypus, will give an idea of their wonderful formation. But this subject might be enlarged upon to the extent of volumes, were we to embrace it in its fullest extent, and even then but a very limited knowledge would be obtained of these marvellous beings.

We will now proceed to give some description of the marine *Polypi*, or at least such of them as are the fabricators of Corals, *Madrepores*, *Gorgonia*, &c. Un-

der these names we open another enchanting volume of nature's lovely works. It is one replete with high-wrought interest, and presents more matter for mental reflection than almost any other part of creation, marvellous as they all are. The writer of this article has, for some years past, been accumulating information on the subject of coral formations; but it is proper to state that the field of actual observation is open to but few, and yet fewer have benefited from it as naturalists when within their reach.

Our countryman Ellis published a valuable work on corals and the corallines. It is nearly the only one of any consequence on that subject; but it wants simplicity, and a natural association in its arrangement as a system; and subsequent discoveries in that branch of nature have rendered it extremely incomplete. The plates, however, are most accurately designed, and beautiful fac-similes of the various species described. Solander, in a work on *Zoophytes*, as also other naturalists and travellers, have contributed much interesting matter relative to the history of coral formations; but, in our opinion, it is to the labours of an eminent French naturalist, Lamaroux, that we are indebted for the best and most natural scientific arrangement of this little-understood subject. He has grappled the difficulties with a vigorous mind, and thrown a charm around it never before presented. From one of his now rare works we therefore propose making a few extracts, and only regret that we cannot transfuse into our language all the spirit and simple eloquence which distinguishes the original. We must therefore content ourselves with attempting a correct, rather than an elegant translation. The title of Lamaroux's work, to which we first allude, is "*Histoire des Polypiers Coralligènes Flexibles*." A history of *Polypi* takes a wider range than this part of the subject requires, in which only such as form *coral* are to be considered. They have been called *Zoophytes* by great authorities, but it is manifestly inaccurate, as the signification of animal plant cannot apply, since the organisation of corals and corallines is purely animal, and possesses no vegetable property beyond a coincidence of external configuration, which would equally apply to many portions of animal structure which present a similar resemblance. To call them "stone plants" would be no better; and to say they are animated stones would still more be cavilled at. It will presently be explained that corals, commonly so called, are formed by certain *Polypi*, who work out the term of their existence on, and never quit during life, the coral, leaving, after death, no more, as it were, than their skeleton, or rather that of the whole colony of *Polypi*. Coral thus being the dwelling, as well as the formation, of these creatures, we propose adopting the term *Polypidom* to express the view we take of the subject. We shall therefore translate the title of Lamaroux's work "*A Treatise or History of the Flexible Polypidoms*," leaving it to the better taste of others to adopt anything more expressive. The term *Polypidom* would equally well apply to the coral and *Madrepore* formations, which are distinguished by their *stony* nature from the flexible *Polypidoms*, whose axis is *horny*; and the architects of these may properly be called coralliferous *Polypi*, in contradistinction to the other species.

Lamaroux truly observes, that, notwithstanding the extensive information of naturalists, philosophers, and

travellers, much yet remains unknown of those *Polypidoms* which people the vast empire of the deep. A very small portion of their *Polypi* have been observed, and entire orders exist whose animals have not, to the present time, been discovered. No light has been thrown on their organisation, their growth, or their precise term of existence; all yet remains in mysterious obscurity respecting the physiology of this singular class of organisation; but that they are wholly *animal* remains no longer a doubt; and the term *Zoophyte*, for the reasons we have assigned, can no longer apply to them.

Polypidoms present one decided never-failing character, that of being the habitation, and forming the most solid part of many thousand living animals, united, and incapable of voluntary separation from each other. These creatures, or *Polypi*, have but one character in common, that of being constantly attached to an animated mass, sharing in, and contributing to, its existence; and, notwithstanding this voluntary attachment to the colony, each individual possessing animal functions of its own, distinct from its neighbour. All the *Polypi* constituting a *Polypidom* participate in its existence, and the sustenance derived by one of these little wonder-working creatures extends its beneficial influence to the most distant point of the colony it forms a part of. It is not easy to understand or account for this; but matter-of-fact observation proves that it must be so; and we are bound to receive concurring evidence in the absence of positive and particular proof to the contrary. And here Lamaroux says—"Some species of *Polypidoms* are found constantly sloping on the southern aspects of rocks, but never on those to the east, west, or north; on the contrary, others only develop themselves on those aspects in general; whatever their situation, their branches appear constantly directed, in the progress of their construction, towards the main sea."

The larger *Polypidoms* are but rarely met with in situations exposed to the shock of violent currents, or full influx of the waves. It is in the caverns of rocks, in submarine grottoes, in the shelter of large and solid masses, and most particularly in those gulfs where the waters are not agitated, that these extraordinary creatures fix their dwelling. Many of them appear not only formed to resist the powerful action of the boisterous surge, but to thrive and delight in it, their bending branches yielding to the movements of the waters, and balancing the animals that form them in the restless medium. Others, again, construct rocky and immoveable habitations, giving them the form of tunnels, and placing themselves in the interior; while some, by their reunion or aggregation, form an extensive stratum, narrow in proportion to its length, but prolonged without interruption, and forming an immoveable dike or wall, for many terrestrial degrees. This usually crosses the great currents of the ocean, whilst its solidity and greatness continually are augmenting, as it were, to overcome the difficulty of its task. Sometimes these rocks of *Madrepore* are curved in a circular form; the *Polypi*, inhabiting them in their interiors, elevate by slow degrees their marble dwellings to the surface of the waters; thus, ever sheltered in their labours, they load, by patient perseverance, the bottom of the deep; but in the higher part of this impenetrable wall openings are left that communicate with the external waters, that the *Polypi* within may be con-

tinually supplied with aliment, and the principal materials for the construction of their submarine habitations.

The fearless navigator, confidently sailing in a sea that former adventurers had indicated as free from rocks, dashes his prow on an unexpected ridge, whose sides are so perpendicular that no sounding can be found at the ship's stern; but, while combating with the fury of the tempest, he happily meets one of these openings which chance, or rather the animal's instinct, has left unclosed; by this he is saved. He enters a harbour of slightly undulating waters, sheltered from the contending storms which, outside the barrier, seem bent on its annihilation, but cannot shake it, and spend their force in air.

The *Polypidoms* do not always rise to the surface of the waters; some extend themselves horizontally on the base of the sea, or pursue its curvatures, spreading ocean's floor with an enamelled carpet of varied brilliant hues; at other times this carpet has only one shade, nearly equalling the Tyrian purple of antiquity. Many of these beings resemble a shrub that winter has despoiled of its verdure, but which spring has renovated with fresh flowers, their branches covered from its base to the extremities with petaled animals, whose beauty vies with the most delicate and richly-coloured blossoms.

The *Polypidoms* are found near the surface of the water as well as at the greatest depths of the ocean. Some exist in parts where the light of the sun cannot penetrate, and there multiply to infinity, notwithstanding the enormous pressure and extreme cold which they must experience at a depth of two or three thousand fathoms. There are strong grounds to presume that their growth is slow in proportion as they are immersed in the water, and that, at five hundred fathoms from the surface of the sea, it would require a century before coral attained the same growth as when only a few yards of fluid covered it.

Polypidoms, like plants, vary with the climate they inhabit. In the colder latitudes the *Cellularia* and *Sertularia* only are to be found, with a few closely-woven *Sponges* and a small number of *Alcyonia*. In the neighbourhood of the volcanic isles of the polar regions, or on those shores exposed to the marine flow and ebb, which, after having been warmed by a tropical sun, has bathed the eastern coast of America, and then directed its course to the western shores of Europe, *Coralina*, *Gorgonia*, and *Isidia*, are met with. The two first multiply a little from sixty to fifty degrees of northern latitude; their numbers then increase to the forty-fourth or forty-fifth degree; and *Gorgonias*, with rampant stems; *Spongias*, with loose tissue, brittle or elastic; and *Millipores*, with foliated and fragile expansions, are found. A little farther the coral reddens the depths of the ocean with its brilliant branches; and this is soon followed by the *Polypæan madrepores*.

It is not, however, before the thirty-fourth degree of northern latitude that these animals commence the development of that grandeur and immensity that presents itself at every step to the extent of a parallel southern latitude. Here they disappear, after having exhibited the same series of phenomena observed in the northern hemisphere.

It is then within the tropics, or in a zone of more than sixty degrees' expansion, that these beings, these animalculæ, scarcely visible to the naked eye, and whose operations uninterrupted proceed, eter-

nally exercise their empire in a medium of never-changing temperature.

From the depths of the ocean they elevate those immense reefs that may ultimately ensure a communication between the inhabitants of the temperate zones. The naturalist visiting these madreporous islands, once covered with the ocean, is astonished at their extent and perfect preservation, so perfect, indeed, that the sea appears to have abandoned them recently; and the same species of *Polypidom* that crowns the greatest heights, and forms the whole island, frequently extends from its shores to an endless distance; so that, when the tide recedes, perhaps an interminable league presents the same *Polypidom* to observation that composes the heads of their mountains. The air, light, and rains, have contributed to destroy the animals of these *madrepores*. Their skeletons alone remain to attest the ancient sojourn of the ocean in these elevated sites, and the slow but incessant diminution of the waters on the planet we inhabit. The greater number of *Polypidoms* are found to originate in the heart of the ocean, and in its numerous divisions, with the exception of the *Naisæ* and the *Ephydriæ*, which inhabit fresh water, whether current or stagnant.

Some of the *Polypidoms* appear to prefer the immediate influence of the atmospheric changes. They are seen on rocks, and on the plants which the tide leaves uncovered, sometimes in such profusion that they all appear concealed under a membranous calcareous covering. These species, however, at least on our own shores, are neither numerous, nor attain to any considerable size.

They almost all suffer from the action of the air. At the period of the great equinoctial tides the sea retires from those rocks it covered many preceding months. When the water first leaves them the *Polypi* are full of life, but suffer and languish as they lose their moisture, nor fail to perish altogether, should the sea remain too long without again covering them. Those whose structure enables them to retire within the recesses of their cells are better enabled to hold out for a longer period, being sustained by the moisture they preserve; but the uncovered *Polypi*, and those whose whole mass is animated like the *Alcyonia*, experience a more rapid alteration, proportioned to the higher temperature and the dryness of the air. Taken in this state of sufferance, and replaced in sea-water, these little animals slowly resume their activity. There are some which do not expand their tentaculæ till the second or third day; whilst those which, immediately after their exposure to the air, have been carefully restored to their natural element in a tranquil spot where the water was not agitated, have soon expanded from their cells, or the mass to which they were attached. It may here be necessary to remark, that naturalists have frequently erred in describing the contracted polypus for one expanded; and so extremely different is their appearance, that such errors may well be excused in those who have fallen into them.

Of the duration of life in these creatures, like all other organised beings, both in the animal and vegetable kingdoms, they have three epochs of existence, their growth, their maturity, and their decline. Some commence and terminate their existence in the short space of a day, perhaps an hour only, while others

live through centuries, setting the tooth of time at defiance. Some of the *Polypidoms* have only this ephemeral life; the existence of others seems eternal and coeval with the world's formation; this observation does not, however, apply to the *Polypi*, as they, separately considered, do not appear to possess a long life, but, on the contrary, many circumstances induce us to believe it of a very limited duration.

In the *Flustra*, *Cellularia*, and *Sertularia*, annual species are found, and others are subordinate to the marine plants that support them. In almost all *Polypidoms* the lower parts are wholly devoid of animalculæ, and in the greater number they are only seen at the extremities. Some there are entirely covered with animated *Polypi* through the summer and autumn, but they then decline, and finally perish with the cold of winter. No sooner, however, has the sun resumed his revivifying influence, than new animals are developed, and fresh branches are produced upon the old ones. The lower portion appears inert, and deprived of all kind of life; the *Flustra*, *Sertularia*, and *Gorgonia*, afford many examples of this. Arrived at the last stage of existence, the *Polypidom* languishes; it has no longer the power to resist the destructive influence of time, or the attack of those natural enemies which the energies of life till then repulsed. Some of these feed on its fleshy envelope; others penetrate to the interior of the axis, and live on its substance, however solid it may be, or, by perforating it in various directions, destroy its support, sending it a wreck to the mercy of the waters, till at last the fragments perish, and are cast upon the shore in a form scarcely recognisable, being reduced to grains of calcareous sand, again destined to become incorporated and rendered subservient to man's use in some other shape.

In the vegetable world plants are found in all latitudes, in all climates, in every soil, whether on the roof of the peasant's cottage, or on the marble dome of a palace: the number of such is, however, inconsiderable; but the majority of vegetables that adorn the surface of the globe require a particular soil and climate. This, however, is not the case with *Polypidoms*; few of them prefer one substance to another as a point of attachment; the greater proportion of these creatures, requiring only one fixed point of rest, attach themselves indifferently to any hard or solid body the sea presents; they are seen on primitive, secondary, and other rocks, sometimes on stems of marine plants, on blocks of lava, fragments of vases, or other antiquities, and even on human skulls. Sometimes these *Polypidoms* wholly envelop fragments of wood that float on the surface of the water; at other times they surround and bury the wrecks of old vessels abandoned in ports and other places; and there are some whose base dividing into numerous fibres, like the root of a tree, penetrate deeply into sandy or muddy shores to find a point of fixation which the surface cannot afford them. In general their base is solid or extended in the corticiferous *Polypidoms*, fibrous in the calciferous, and non-existing, or nearly so, in the carnoid and celluliferous classes; thus, as this part only serves the *Polypidom* as an anchor, we may consider it as a means employed by nature to prevent those beings, deprived of locomotive power, from becoming the sport of the waves. In this respect only, independent of their external configuration, do they resemble vegetable productions. The forms of *Poly-*

pidoms are too various to admit of a general description, as the following outline will exhibit.

The celluliferous appear aggregations of isolated cells, placed on the surface of marine bodies, or else cells so united as to form by their adhesion to each other a thin crust on the surface of the thalassioophites or testaceous molluscs, and frequently appear in leafy diversified expansions; sometimes these cells are placed on stems like leaves on their branches; in others they appear in the form of very long branching or simple tubes, separated from each other in their upper part, and united in their lower, to form stems, as well as a firm foot or root, by which they adhere to some solid immovable base.

In the calciferous there also exist great disparities; some of them ramify like shrubs, whilst others divide in numberless dichotoma, or resemble a painter's brush; some take the form of an umbrella or an open fan; some are simple, others branched; some articulated, others compressed; some flat, and others cylindrical.

The corticiferous display an equal variety; there are spongia that spread in thin patches on the rocks and marine plants; others form themselves into globular masses, or are hollowed in the form of tunnels; many rise in tubes like organ-pipes, and some divide in the form of thick leaves. What an infinite variety of form exists between the *Gorgonia* with its simple unbranched stem, and others whose anastomosed branches resemble the reticulations of net-work, or as in the flabellated andyomena, in which they are so regularly and elegantly designed, that they resemble delicately worked lace.

The isidia has an alternately stony and cartilaginous stem, bearing some resemblance to the vertebra of an animal of more perfect organisation; others in appearance may be compared to shrubs despoiled of their leaves, but covered with flowers, whose snowy whiteness is heightened by being contrasted with the deep and brilliant red of the branches.

In the carnoid *Polypidoms* differences almost as numerous exist, but they are much less known than those described in the preceding orders.

Having thus briefly given a general idea of the form of *Polypidoma*, a more general description will scarcely be expected; for, if this be impracticable in one division, it must remain so with regard to all other of these animal architects.

With respect to the size of *Polypidoms*, we find some so minute, that it requires the aid of glasses to discover them, whilst others are as elevated as the mountains, their heads raised to midway air, their base fixed in the sea's foundation to a depth unfathomable; such are the madreporeous islands so numerous in the south-eastern ocean, where they are hourly augmenting by the incessant and inconceivable labours of countless myriads of *Polypi*. Some geologists have imagined that these isles were only the summits of submarine mountains that had been covered, or, as it were, encased by *Polypidoms*; but submarine mountains, the almost perpetual source of subterranean fires, are found in all latitudes, and greatly vary in their extent and in their forms. The madreporean islands, on the contrary, exist only within the tropics, and present forms constantly analogous to each other, nor are they ever overturned by earthquakes or volcanic eruptions. These are described in the following extracts by veracious travellers who have traversed those seas.

"The whole group of the thousand islands, and indeed the greater part of those whose surfaces are flat in the neighbourhood of the equator, owe their origin to the silent, unseen, never-ceasing labours of *Polypi*; their calcareous habitations are constructed in an infinite variety of forms, yet with that order and regularity, each after its own kind, that is so discernible to the minute inquirer in every part of creation. It is true the eye may easily be convinced of the fact; but it is difficult for the human mind to conceive the possibility of animals, so apparently insignificant, being endowed with the power, much less of being furnished in their own bodies with the materials of building up the immense fabrics which, in almost every part of the Eastern and Pacific Oceans lying between the tropics, are met with in the shape of detached rocks, or reefs of great extent, just even with the surface of islands already clothed with plants, whose roots are fixed at the bottom of the sea several hundred feet in depth, where light and heat so very essential to animal life, if not excluded, are sparingly received and feebly felt.

"Thousands of such rocks, reefs, and islands, are known to exist in the Eastern Ocean, within and even beyond the limits of the tropics. The eastern coast of New Holland is almost wholly girt with reefs and islands of coral rocks rising perpendicularly from the bottom of the abyss. Captain Kent, of the *Buffalo*, speaking of a coral rock many miles in extent, on the south-west coast of New Caledonia, observes, that it is level with the water's edge, and towards the sea as steep as the wall of a house; that he sounded frequently within twice the ship's length with a line 150 fathoms (900 feet), without being able to reach the bottom.

That delightful writer and intelligent traveller, Captain Basil Hall, in his voyage to the Loo Choo Islands, has also made some interesting remarks on the examination of a coral reef; he observes that during the different stages of one tide the changes it undergoes is truly surprising. When the tide has left it for some time it becomes dry, and appears to be a compact rock, exceedingly hard and ragged; but as the tide rises, and the waves begin to wash over it, the coral worms protrude themselves from holes which before were invisible. These animals, he says, are of a great variety of shapes and size, and in such prodigious numbers, that in a short time the whole surface of the rock appears to be alive and in motion. The most common worm is in the form of a star, with arms from four to six inches long, which are moved about in all directions, probably to catch food. Others are so sluggish that they may be mistaken for pieces of rock, and are generally of a dark colour, from four to five inches long and two or three round. When the coral is broken about high-water mark it is a solid hard stone; but if any part of it be detached at a spot where the tide reaches every day, it is found to be full of worms of different lengths and colours, some being as fine as a thread and several feet long, of a bright yellow, and some of a blue colour; others resemble snails, and some are not unlike lobsters in shape, but soft, and not above two inches long.

The growth of coral appears to cease when the worm is no longer exposed to the washing of the sea. Thus a reef rises in the form of a cauliflower, till its top has gained the level of the highest tides, above which the animal has no power to advance, and the

reef, of course, no longer extends itself upwards; the other parts, in succession, reach the surface, and there stop, forming in time a level field, with steep sides all round. The reef, however, continually increases, and, being prevented from growing higher, extends itself laterally in all directions; but, the growth being as rapid at the upper edge as it is lower down, the steepness of the face of the rock is still preserved. These are the circumstances which render coral reefs so dangerous to navigation; for, in the first place, they are seldom seen above the water; and, in the next, their sides are so perpendicular that a ship's bow may strike against the rock before any change of soundings has given warning of the danger.

To the remarks of these travellers we will add those of another, an accurate observer of nature, whose frequent visits to the coast of New Holland fully confirm these accounts. His diffidence has hitherto prevented the public from enjoying the animated description he gives of the wonderful phenomena coral formations exhibit. We have, nevertheless, his permission to extract an observation from his manuscripts, which does not appear to have been made by any other naturalist or traveller with whom we are acquainted, or whose publications have appeared. It is the magic effect produced by the almost instant growth of vegetable matter on these rocks; for, no sooner have the *Polypi* become checked in the upward progress of their eternal labour, by having reached the level of the sea, and are forced to work their restless course beneath its surface, than the upper world, jealous, as it were, of territory thus forced upon it, immediately claims it, and peoples it anew. It is rapidly clothed with verdure; an artificial soil is quickly deposited by the exuviae of marine animals and plants. The excrement of birds, who flock in countless myriads to feast upon the sea's *rejetamenta*, greatly assists to increase the stratum of soil, leaving with it the seeds of plants and trees, that, springing into life, quickly attain maturity, in such congenial ground, and, in their turn, contribute largely to their parent soil, as the succeeding changes of season, with unerring truth, divest them of their leafy garb. By these causes repeated strata of earthy matter are deposited; a verdant island rises, smiling in the face of desolation, and bids defiance to the angry storm, forming possibly a future asylum to man, or the subject of a state's contention.

Another fact, less easily accounted for, but proving the infinite goodness of God, is, that on these islands fresh water is almost always to be found in the hollow basins below the level of the sea, and in the cavities formed in the earthy cavities on the face of the island, and generally in the most open situations. May not this be caused (without any very extravagant stretch of hypothesis) by the immense pressure of the surrounding medium forcing the water through the rocky interstices, and filling these basins by a species of infiltration, during which much of its saline particles are purged, and it is ultimately purified by the heat of the solar rays, which crystallise the remaining salt, and precipitate it to the bottom of these gigantic evaporating basins, immediately supplying vegetation and animal life with their most necessary and salutary aliment, water, in addition to that which the bounteous streams of heaven seasonably supply?

Montgomery, in his poem "The Pelican Island,"

so elegantly and so truly exemplifies these mighty fabrics, that such of our readers as have not read that portion will thank us for this opportunity of doing so.

"Compared with this amazing edifice,
Raised by the weakest creatures in existence,
What are the works of intellectual man?
Towers, temples, palaces, and sepulchres;
Ideal images in sculptured forms;
Thoughts hewn in columns, or in domes expanded,
Fancies through every maze of beauty shown;
Pride, gratitude, affection, turned to marble
In honour of the living or the dead;
What are they? fine-wrought miniatures of art,
Too exquisite to bear the weight of dew
Which every morn lets fall in pearls upon them,
Till all their pomp sinks down in mouldering relics;
Yet in their ruin lovelier than their prime;
Dust in the balance, atoms in the gale,
Compared with these achievements in the deep,
Were all the monuments of olden time,
In days when there were giants on the earth.
Babel's stupendous folly, though it aimed
To scale heaven's battlements, was but a toy,
The plaything of the world in infancy:—
The ramparts, towers, and gates of Babylon,
Built for eternity—though, where they stood,
Ruin itself stands still for lack of work,
And desolation keeps unbroken Sabbath:—
Great Babylon, in its full moon of empire,
Even when its 'head of gold' was smitten off,
And from a monarch changed into a brute;—
Great Babylon was like a wreath of sand
Left by one tide, and cancelled by the next:—
Egypt's dread wonders, still defying Time,
Where cities have been crumbled into sand,
Scattered by winds beyond the Libyan desert,
Or melted down into the mud of Nile,
And cast in tillage o'er the corn-sown fields,
Where Memphis flourished, and the Pharaohs reigned;
Egypt's grey piles of hieroglyphic grandeur,
That have survived the language which they speak,
Preserving its dead emblems to the eye,
Yet hiding from the mind what these reveal;—
Her pyramids would be mere pinnacles,
Her giant statues, wrought from rocks of granite,
But puny ornaments for such a pile
As this stupendous mound of catacombs,
Filled with dry mummies of the boulder worms."

We will now proceed with an account of the coral formations, from which we have somewhat deviated, we trust, however, not unprofitably to our readers, as every additional illustration of these interesting facts will be duly appreciated.

Lamarroux observes—If we compare this polypæan mass, that rises from the immeasurable depth of the ocean to a level with its surface, shooting into the air under the form of mountains, to the *Melobesia*, to the *Cellepora*, which has only the appearance of a white spot, merely a minute deposit of calcareous particles, how striking is the difference! what an infinity of intermediate stages of formation must exist between the two extremes! Generally speaking, the cellular *Polypidoms*, as well as the calciferous and carnoid, seldom exceed a yard in height, and usually are much smaller. The corticiferous are sometimes many yards in height. It is then in the madreporic *Polypidoms*, those that are wholly stony, that we must seek for giants in this department of the animal kingdom; whilst their architects are so small as frequently to elude the naked eye, and can only be distinguished by a magnifying power; in some groups of *Polypi* they even escape the best optical instruments, and leave us only analogy and reason to demonstrate their being and existence. It has, however, on the authorities we have quoted, been shown that *Polypi* exist of a very considerable size; none of them, however, exist on our own coasts, or in the north of Europe, though it is not improbable that the equinoctial seas may enclose many species as yet undescribed.

If, notwithstanding the energetic influence of air and light on all created beings, and particularly those of submarine existence, we may judge, from the hues that still remain to them in the cabinets of naturalists, their colours must be varied and brilliant in the extreme on their natural sites, in the fathomless profundity of the sea.

The atmospheric fluids rapidly affect the colour of *Polypidoms*; it is by no means uncommon to see a *Sertularia*, of a brilliant yellow when first discovered in the sea, fade and become a tarnished brown three hours after it has left it: sometimes the change is much more rapid. Sponges, of a lively lilac when covered with the water, become nearly white when exposed a few minutes to the contact of air and light. There are, however, *Polypidoms* preserved many years in museums whose colours appear more permanent; their stems are of a bright and deep hue, or their rind of a brilliant colour; we can readily suppose this envelope to have been infinitely brighter while the *Polypi* were in life. It is not, however, impossible that, like many of the marine *Floridas*, some of these animal productions may assume more varied hues and brilliant tone of colouring, from the combined effect of light, humidity, and their first stage of decomposition.

It is always to be remembered that these considerations of *Polypidoms* are not applicable to the *Polypi*, whose dwelling they form; these latter are sometimes of the clearest transparency, at others this pellucid appearance is clouded and whitish; they frequently partake of the colour of the animated mass to which they belong, only differing in shades according to the various parts of organisation. In many of the *Gorgoniæ*, and in some of the *Alcyoniæ*, the colour of the *Polypi* is entirely different from that of the *Polypidom*, and forms an elegant contrast. In general their brilliancy and transparency become tarnished and opaque as soon as they are deprived of life, or exposed to atmospheric influence.

The unreflecting mind may ask what is the utility of these creatures; too small to afford material nourishment to others, yet capable of rendering venomous those which partake of the little they can supply? When devoured by fishes, they have caused maladies so serious and so general that travellers in those regions will not touch fish, knowing it, by fatal experience, to be unwholesome and of a baneful quality. Molluscous animals taken from the madreporic rocks have been found to possess an insufferable stench; this may be accounted for by the *Polypi* being in a state of decomposition, and their feidness is then sufficiently powerful to cause vertigos and even suspended animation, as has been experienced by Lamarroux while preparing specimens of the *Antipathes myriopylla*, which a friend had sent him from Nice.

Sometimes the *Polypi* wholly envelope, in a calcareous coating, marine plants; and, by obstructing the pores necessary for their aliment, cause them to perish in a living tomb. Other innumerable instances might be adduced, such as causing shipwreck, the choking up of harbours, &c.

But He, who formed the universe, created nothing in vain! His works all harmonise to blessings, unbounded by the mightiest or most minute of His creation. Each day displays to the properly constituted mind new proofs of His wisdom in new developments of His plans, and gives fresh force to the conviction that our ignorance alone must obscure our view when we cannot comprehend His aim of eternal good.

On land the vegetable tribes absorb the carbonic acid our inhaleds have created, and return us the life-giving oxygen. In the bosom of the deep the *Polypi* absorb the calcareous salts brought from the various countries whose coasts it has visited, which salts, by a continued accumulation, might otherwise prove as destructive to its inhabitants as the carbonic acid proves to those on land; but the *Polypi* collect, decompose, and render them insoluble to the surrounding element which their labours have thus purified; they unite them into a mass of such extent that in the progress of time the domain of man becomes enlarged, and vegetation blooms and blesses with its fruits on the structures that have ceased to serve them.

Let those, who thoughtlessly ask of what use are these creatures, learn the fact, could no other be adduced, that to the assistance of lime we owe the elegance and solidity of our buildings, particularly the latter. The calcareous stone or carbonate of lime, that Proteus of the mineral world, is wholly wanting in the equatorial regions; may we not therefore be permitted to consider these madreporous *Polypidoms* as destined by Infinite Wisdom to supply its absence? At Djeddah in Arabia, and on many other parts of the coasts of the Red Sea, the houses are constructed entirely with blocks of beautiful madreporite. In the Indian isles, as well as in those of the Indian ocean, and in many other parts, the madrepores are used for the manufacture of lime. At Martinique also they dredge them for that purpose from the bottom of the sea.

What could we substitute for sponge in domestic uses? where find a substance equal to this polypcean production in the property of imbibing water without any diminution of elasticity or alteration of its nature? The sponges we have in use are found in the equinoctial seas of both worlds, and in the warmest parts of the temperate zones; they are a considerable object of commerce, many of the Mediterranean isles have no other product to export.

In France, and throughout Europe, the *Corallina officinalis* is used as a powerful anthelmintic; it is known under the name of *Coralline* of Corsica, and brought from the different parts of the Mediterranean; it is very abundant on the western coasts of France, as also on the shores of England. Sir Humphry Davy has remarked that it has a fattening tendency, as well as others of its family.

The inhabitants of Iceland, celebrated for its frosts and its volcanos, make use of a flustra, in the form of snuff, to excite sneezing, either on account of its agreeable smell, resembling violet, or as a preservative against the scurvy, so dangerous in its ravages in those regions.

On that well-known *Polypidom*, the RED CORAL (*Isis nobilis*), true stony coral of authors, we must make a few short remarks. It is so well known as a material from which numberless elegancies of life are formed, that a particular description of it were needless. In all ages and in all countries mankind have acknowledged its beauty. Warriors have employed it in the ornamenting of their weapons; men and women in the decoration of their persons and houses; the physicians of the middle ages looked upon it as a universal remedy; and the priests of ancient religious sects esteemed it as an object acceptable to the gods.

Coral then may be a name retained to distinguish

the above species *par excellence* from the other *Polypidoms* of a stony texture. Its natural figure is tree-like; it is inarticulated, the axis stony, stiff, and susceptible of the highest polish; the rind is fleshy, becoming chalky and very friable by desiccation, and always adhering to the axis; this is equal to marble in solidity, which, being formed of concentric layers, they become perceptible by calcination; its surface is more or less striated; the striæ parallel and unequal in depth.

A reticulated body, formed of small membranes, with numberless vessels and glands filled with a milky juice, appears to unite the rind with the centre. This reticulated body is found in all corticiferous *Polypidoms*; the rind is of a less deep colour, of a soft substance, and formed of small membranes and slender filaments; it is pierced by tubes or vessels, and covered with tubercles, which are thinly scattered and have a large base, the summit of which is terminated by an opening divided into eight parts. In the interior is found a cavity which contains a white and almost transparent polypus, its mouth surrounded by eight conical tentacula slightly compressed, and ciliated on their borders.

This coral is found in different parts of the Mediterranean and Red Seas, it grows in all directions, and each trunk forms a perpendicular to the level from whence it springs; it attaches itself to all rocks, whatever may be their nature; it is also found on unfixed bodies, such as fragments of lava, stone vases, broken glass, and specimens have been exhibited in museums adhering to a variety of bodies.

When coral is once detached and at the mercy of the waves, it soon loses its polypiferous rind; to enable the constructors of this brilliant edifice to labour for its increase, it is indispensable that it should be fixed; their work does not, however, advance with a rapidity equal to that of the madreporic *Polypi* in the Indian sea, or the immense Eastern Ocean, whose labours, in the short space of a few years, close the entrance of marine ports, and raise those gigantic reefs we have already been describing, on which many vessels, sailing in those distant regions, have struck and perished.

Coral is found at different depths in the bosom of the waters, but, notwithstanding the density of the medium in which it exists, all aspects are not suitable to its increase. On the coasts of France it covers those rocks that face the south; it is rarely met with on those having an eastern or western aspect, and never in a northern one. It is never found at less than three or four yards below the surface of the sea, nor ever at a greater depth than 350 yards.

In the straits of Messina coral prefers an eastern aspect, on the south it is seldom found, and still less on the rocks of the north or west. They there fish it from a depth of 100 to 200 yards. In those straits, immortalised by Homer and Virgil, the solar rays strike more perpendicularly than on the coast of France, their heat penetrates to a greater distance, and the coral is found even deeper than 300 yards; but then its quality no longer compensates for the risks and numerous difficulties attending the procuring of it.

On the north coast of Africa it is not sought beyond thirty or forty yards in depth, and at a distance of three or four leagues from shore; they abandon it when it reaches 250 or 300 yards.

The coral is generally of a more beautiful colour

in shallow waters which easily admit the light, than where the immense column of water, by absorbing all the luminous rays, deprives it of the energetic influence exerted over all animated beings by that beneficent medium unceasingly emanating from the sun.

Coral on the coasts of France, being perhaps better chosen than in other countries, has the reputation of possessing the liveliest colours and the greatest brilliancy; that of Italy, however, rivals it in beauty; on the Barbary coasts it attains greater thickness, but the colour is inferior.

Fifteen different varieties are distinguished in the course of commerce; these, from their colour and degrees of beauty, obtain the several names of *froth of blood*, *flower of blood*, *first*, *second*, *third blood*, and so on.

At Trapani in Sicily, where the principal coral fishery of the island is carried on, it is managed by a very ingenious and simple contrivance. To the centre of a large wooden cross is fixed a stone sufficiently ponderous to carry the cross to the bottom of the water. Pieces of small strong net are tied to each limb of this cross, which is poised horizontally by a rope, and then let down into the sea. As soon as it is felt to touch the bottom, the rope is made fast to the boat, which is then rowed about over the beds of coral, and the great stone breaking the branches of the rocks, they become entangled in the net-work, are thus secured, and wrested from their birth-right.

CORALLINA is a plant-formed *Polypodium*, articulated, branched, and trichotomous, axis or interior wholly composed of horny fibres; rind cretaceous and cellular, the cells being invisible to the naked eye. Former authors had united under the name of *Corallines* all the flexible *Polypidoms*, such as the *Sertularia*, *Tubularia*, &c. Later writers on the subject deem it advisable to reserve this denomination for one order in this class of creation, a close observation of the various characters distinguishing the order has induced a separation of them into genera, and to assign particularly to one genus the appellation of *Corallina*.

The *Corallines* of Europe have their polypæan cells so very small and so subject to obliteration, that it is not extraordinary they still remain undiscovered; in the equatorial seas the cells are much larger, and frequently visible to the naked eye. Lamaroux observes that rambling over the Calvados (a range of rocks on the coast of Normandy), he frequently found a very large *Corallina*, a variety of the *C. officinalis*; it was covered with simple transparent filaments, which had a movement peculiar to themselves, they disappeared with the slightest agitation of the water, or when the *Polypidom* was exposed to the air; in the latter case he was never able with the strongest magnifier to discover the slightest remains of these filaments, the point they had been attached to, or the cells they might have issued from, supposing them to have been *Polypi*. This, however, remains doubtful, as it was only in the spring season he ever observed them, and then only a few particular individuals. In winter he never could discover them at all.

In the *Janias* and *Corallina* are frequently observed small globular bodies, more or less voluminous, and varying in their substance; the tubercles that are found on the *Amphiroa*, *Halimeda*, *Udotea*, and *Melobesia*, appear analogous. Ellis imagined them air-vessels to support them in the water; but these vesi-

cles are rarely empty, they have even been found quite solid or filled with small grains of an unknown nature. They are more probably ovaria, enclosing the germs of future *Polypidoms*, and indeed all the flexible species appear thus to multiply.

The *Polypidoms*, to which the generic name of *Corallina* is reserved, have always articulated stems, more or less compressed, more or less branched, and constantly trichotomous. Their colours, when fresh, generally incline to red or purple; exposed a very short time to the atmospheric action, light and humidity, they display a variety of prismatic hues, each more brilliant than the other, from the lightest and most brilliant rose-colour to a dull brown, greenish, or only with a tinge of red; infinite gradations are observable, but they all become bleached in the air.

Polypidoms of this genus are found in all latitudes, at every depth, and on all the coasts of the principal divisions of the world. They are, however, larger in the equatorial seas, more brilliant in their hues, and more elegant in their form. Fixed usually on rocks, or other hard and almost immovable substances, they resist the influence of the waves, and are very rarely detached from their bases or cast on shore. Only one or two species of *Corallina* are parasites on the *Thalassiphytes*, whilst nearly the whole of the *Janias* are found upon these vegetables.

Corallines vary but little in their height; they sometimes exceed, but seldom, four inches, and are in general less.

The *Corallina officinalis* was formerly used as an anthelmintic or worm-destroying medicine, but at the beginning of the eighteenth century it seemed nearly to have fallen into disuse in France; at a later period it was again brought into vogue from the reputation of the *Fucus helminthocorton*, vulgarly called moss of Corsica, whose properties seem to be of the same nature, and a chemical analysis of the *Corallina officinalis* does not very essentially differ.

In the Philosophical Transactions, Mr. Hatchet gives the following account of his chemical experiments on what he terms *Zoophytes*. He says *Madrepores* and *Millepores* (like several of the shells) are formed of a gelatinous and membranaceous substance hardened by carbonate of lime, the difference consisting only in the mode in which these materials are combined; that in the *Tubipora*, *Flustra*, and *Corallina*, some phosphate of lime is mixed with the carbonate; that in the *Isis*, the basis is a regularly organised, membranaceous, cartilaginous, and horny substance, hardened by carbonate of lime, one species only, the *Isis ochracea*, yielding also a small proportion of phosphate of lime. That the hardening substance of the *Isis nobilis*—red coral, is likewise carbonate of lime with a small portion of phosphate; but that the matter forming the membranaceous basis consists of two parts, the interior being gelatinous and the external a complete membrane, so formed as to cover the stem in the manner of a sheath or tube. The other *Gorgonias* consist of a horny stem coated by a membrane, which is hardened by carbonate of lime. Sponges are of a nature similar to the horny stems of the *Gorgonia*, and only differ from these and from each other by the quality of the texture. And, lastly, that the *Alcyonia* are likewise composed of a soft flexible membranaceous substance very similar to the cortical part of some of the *Gorgonias*, and in like manner somewhat hardened by carbonate slightly mixed with phosphate of lime.

From this mass of evidence we collect in general, that the varieties of bone, shell, coral, and the numerous species of *Polypidoms* with which the last are allied, only differ in composition by the nature and quantity of the hardening or ossifying principle, and by the state of the substance with which this principle is mixed or connected; the gluten or jelly which cements the particles of phosphate or carbonate of lime and the membrane, cartilage or horny substance which serves as a basis, appearing to be only modifications of the same substance, which progressively graduates from a viscid liquid or gluten into a gelatinous substance; this again by inspissation, and by the more or less perfect degrees of organic arrangement, forms the varieties of membrane, cartilage, and horn, forming the peculiar differences of the several species.

In the matchless Museum of the Royal College of Surgeons of London, several elegant preparations of *Madrepore* and calcareous *Polypidoms* may be seen, in which it is manifest that when the carbonate of lime has been absorbed by a chemical operation, the animal matter remains, still exhibiting its original form; but, being divested of its hardening matter, is a mere gelatinous substance.

Lamaroux has constituted four classes of flexible *Polypidoms*, the

FIRST CLASS is that of the celluliferous, whose *Polypi* are found in shelly or non-irritable cells. It is divided into three orders, beginning with that whose cells are apparently isolated, and comprehends the *Flustra*, *Cellularia*, &c. The second order includes all those with coalescent or united cells, formerly styled *Sertularia*; the *Tubularia* forms the third order, their cells being tubular and horny, simple or branching, with one or many openings. The

SECOND CLASS, whose *Polypidoms* are styled calciferous, are of a chalky substance mixed with that of animal, and continuing apparent in every stage; this class also contains three orders, the first of which has, like the *Tubularia*, the *Polypi* at the extremities of the stems and branches, but, being less horny and more calcareous, forms an intermediate link between the last order of the first class and the second order of the present class, whose *Polypidoms* are very cretaceous or chalky, but whose *Polypi* are not apparent; they are articulated, which distinguishes them from the third order of this class, in which they are not articulated.

In concluding this article we are enabled to add, that an able naturalist is about to publish, at no very distant period, a systematic arrangement of these wonder-working creatures. It is a subject on which more may be said, and less is hitherto known, than any other; but the necessary information and observation is so difficult of access, that few persons have ventured to explore its mazes; but the immense impetus now given to the study of nature by the united labours of eminent men, in every part of the world, will render her paths more easy to tread, and enable the student to unlock the storehouse of her treasure.

POLYTHALAMACEA, is the third order of the first class, *Cephalophora*, of the French naturalists; it includes the genera, *Orthocera*, *Belemnites*, *Conularia*, *Conolites*, *Orthoceras*, and *Baculites*; these constitute the first family, under the name of *Orthocerata*. The second family, *Lituacea*, includes the genera *Ichthiosarcolithes*, *Lituola*, *Spirula*, *Hamatites*, and *Ammonoceratita*. The third family, *Cristacea*, comprise

the genera *Crepidulina*, *Oreas*, and *Linthuris*. The fourth family, *Ammonacea*, includes the genera *Discorbites*, *Scaphites*, *Ammonites*, and *Simples*. The fifth family, *Nautilacea*, consists of the genera *Orbulites*, *Nautilus*, *Polystomella*, and *Lenticulina*. The sixth family, *Turbinacea*, includes the genera *Cibicides* and *Rotulites*; and the seventh family, *Turriculacea*, possesses only one genus, *Turritites*.

Under the different generic names a more full description is given of each of these molluscs, and it will be seen that the greater number of them are only known in a fossil state; the most common recent species, such as the *Spirula* and *Nautilus*, will give an idea of the whole order, and why it has been called *many-chambered*. The general characters of these shells are, the body of the animal being contained more or less in the last-formed division, the shell is straight, or more or less rolled upon the same plane, divided by chambers or septæ, and these perforated with one or more syphons or holes. The entire order is established upon the imperfect knowledge possessed of the animals of the *Nautilus* and *Spirula*, to which analogous reasoning approximates the other genera. The arrangement of the genera constituting this order has been guided by the curvature of the spiral cone, the first straight, the others being gradually rolled upon the same plane until no trace of it appears externally, as in the *Nautilus*.

POMADERIS (Labillardière). A genus of evergreen shrubs from New Holland, having pentandrous flowers, and belonging to *Rhamnaceæ*. They are in greenhouse collections, and are treated like other plants from the same quarter of the world.

POMATHORINUS, a genus of *tenuirostris*, or slender-billed birds, bearing some resemblance to the sugar-eaters, but still sufficiently distinguished from them to be reckoned a separate genus. The characters are: the bill long, slender, straight at the base, but slightly bent towards the top, very much compressed in the distal part, but without any notch, and the culmen of the upper mandible with a distinct ridge. The nostrils pierced obliquely near the base of the bill, and partly covered by an oblong membrane. The wings of moderate length and rounded; the tail long and also rounded. The feet with three toes to the front and one to the rear, the middle front is the longest, but the hind one the stoutest of the whole. The claws on all the toes much compressed, crooked, and sharp at the points. All the known species, of which there are several, are forest birds, natives of the Eastern islands and Australia; but little or nothing is known of their manners or their feeding. The species first discovered were classed with the bee-eaters, by the describers of the time; but they do not even belong to the same family, as the bee-eaters have the feet syndactylic, and these birds have not.

P. temporalis was discovered in New Holland by Brown, during Flinders' voyage, in the early part of the present century; but it most likely exists in other parts of the east. Its length is about ten inches and a quarter; its tail pretty long, and its wings short. The upper plumage is yellowish-ash, passing into dull yellow on the under part. The front, under the head, throat, and breast, are white, a thin line over the eye and the tail-feathers are black, but the latter have the tips white. The bill is black at the base, and whitish at the top.

P. superciliosus is another Australian species, for

the knowledge of which we are indebted to the same illustrious naturalist. It has a considerable general resemblance to the former, but it is considerably smaller. Its length is seven inches and three quarters. The upper part is brownish yellow; the dark streak over the eye extends to the nape; the throat, breast, and anterior part of the belly are white; and the bill and feet are black.

P. montana. This species has been observed in the wooded parts of the mountains of Java, at the height of seven thousand feet above the level of the sea; and it is probable that it also exists in the elevated parts of the adjacent islands, and in New Guinea. Its total length is seven inches and a half; its general colour maroon; its head blackish with a white eye-streak; and its throat and breast pure white.

P. Isidorii is a native of New Guinea, and though it has the same generic characters, it differs considerably in appearance from any of the others. Its general colour is maroon, very rich on the wings and tail, paler on the throat and breast, duller on the belly, and mottled a little with grey on the head and back. The total length is about eight inches; the bill is an inch in length, of a yellow colour, very much compressed toward the tip, and with the margin of the upper mandible overlapping the edges of the under one. The tarsi are very stout for the size of the bird; they are covered with large scales in front, and of a reddish brown colour. The toes are stout, of the same colour as the tarsi, and furnished with compressed and crooked yellow claws. The tail consists of ten feathers, is wedge-shaped at the extremity, and nearly four inches long; so that when the length of the bill and tail are subtracted, there remains little more than three inches for the body and head of the bird. The wings are short, and all the quills nearly of equal length, the first being the shortest in the wing.

This bird is easily obtained in the woods of New Guinea, from which specimens were first brought by the French. It is a bird of very peculiar structure, from the length of the bill and tail, the shortness of the wings, and the fact of their being nearly squared over. In these respects there is hardly any other bird that can be compared with it; and, although nothing is known of its habits, there must be a peculiarity of habit answering to its peculiarity of structure. It must be quite incapable of long-continued flight, and thus it cannot move from island to island unless where these are separated from each other by narrow channels. The strength of the tarsi and toes, and the larger scales on the former, might lead to the supposition that it is a ground bird, but the form of the claws are against that. The genus altogether is one of the many peculiar ones of the eastern islands, to which we have nothing corresponding in any other region.

POMEGRANATE is the *Punica granatum* of Willdenow, a fruit-bearing shrub indigenous to the south of Europe, and which in the natural system constitutes an order by itself. The pomegranate, so called from its fruit being likened to an apple full of grain, has received its generic name either from the scarlet colour of its flowers, or in reference to its Punic habitat, the plant being originally found on the northern shores of Africa. It has been long an inhabitant of our gardens, but valued for its fine flowers rather than for its fruit, which never ripen thoroughly

in this country. They are usually planted against south walls, and are easily propagated.

POMPIDIDÆ (Leach). A family of aculeated hymenopterous insects, belonging to the sub-section *Fossoreæ*, and having the hind legs long, the antennæ filiform or setaceous, and often curled up spirally at the tips in the females; the abdomen is ovoid or oval, and attached to the thorax by a narrow and very short peduncle; the lower jaws and lip are straight, and of a moderate length; the collar is transversely quadrate or longitudinal; the hind margin being nearly straight, and extending as far as the base of the fore wings. The family is of considerable extent, and comprises species varying considerably both in their size and colours; they do not appear to be confined to particular districts of the globe, but prefer warm and sandy situations, in which the females construct their nests by burrowing in the earth; they generally provision their nests with spiders, but occasionally with other insects which they have wounded with their stings, and which serve for the food of their progeny, which are produced from eggs deposited separately in the provisioned cells; some species also make their nests in burrows which they find already formed in wood. They are extremely active in their movements; and whilst the females are in search of their prey, they may be observed constantly running along the ground, shaking their wings, or taking short flights. The males are generally smaller than the females; the latter are provided with an extremely powerful sting, and the wounds which they make with it are very painful.

We have, on various occasions, noticed the great solicitude exhibited by female insects in the construction and provisioning of the nests, formed, not for their own residence, but for their future young. The following observations, extracted from the note book of the writer hereof, present another instance of the same kind. "September 17. Observed a very small specimen of *Pompilus fuscus*, at the foot of a perpendicular sand-bank, at Coombe, dragging a seemingly dead ant (*Formica Herculeana*), much larger than itself, to its burrow; on reaching the foot of the bank it quitted the ant, and, as I thought, flew away, but it was only to reconnoitre and discover the nearest way to its nest, situate half up the bank. It then returned to the ant, and seizing it in its jaws began, tail foremost, to drag it up the bank, the uneven surface of which, however, caused it several times to overbalance itself, and fall down again to the foot of the bank. This, however, seemed not to intimidate it, for it as often commenced the re-ascent, endeavouring at the same time to avoid the uneven parts which had caused its downfall. I watched it thus occupied for a length of time, and have little doubt that it ultimately succeeded in reaching the nest, although my attention was attracted away by other objects."

The family comprises the genera *Pepsis*, *Ceropales*, *Pompilus*, *Salix*, *Planiceps*, and *Aporus*. Those printed in italics being British. The genus *Pompilus*, Fabricius, comprises those species which have the maxillary palpi longer than the labial, the upper lip concealed beneath the clypeus and the wings, with four sub-marginal cells. There are twenty-six British species, including the type *Sphex viaticus* (Linnaeus), a handsome insect, varied with red and black, which is very common on Hampstead Heath and elsewhere.

PONTEDERACEÆ. A small natural order in-

cluding only three genera, and of which there are ten species. They are aquatic plants, natives of the East Indies, tropical Africa, and North and South America; they are ornamental, and may be easily cultivated in an aquarium; their properties are unknown, and they have not hitherto been applied to any useful purpose. The genera here united are *Pontederia*, *Heteranthera*, and *Leptanthus*. The species of the two latter may be cultivated in the open air.

PONTIA (Fabricius). An extensive genus of butterflies, belonging to the family *Papilionidæ*, and distinguished by having the lower wings formed into a gutter for the reception of the abdomen; the palpi nearly cylindrical, slightly compressed, with the last joints of nearly equal length, and the club of the antennæ ovoid. The caterpillars are naked and destitute of the fleshy retractile appendage observed on the neck of the caterpillars of the genus *Papilio*. The genus comprises the white butterflies, so common in our gardens and fields, the larvæ of some of the species feeding upon and occasionally entirely destroying our cabbages, brocoli, cauliflower, &c. They are, however, subject to the attacks of various parasitic insects, especially the *Microgaster glomeratus*. "Small birds" also, observes Mr. Haworth, "destroy incredible numbers of them as food, and should be encouraged. I once observed a titmouse (*Parus major*) take five or six large ones to its nest in a very few minutes. In enclosed gardens sea-gulls, with their wings cut, are of infinite service. I had one eight years, which was at last killed by accident, that lived entirely all the while upon the insects, slugs, and worms he found in the garden. Poultry of any sort will soon clear a small piece of ground, but, unless they are of the web-footed kind, they do much damage by scratching the earth."

The most common species of this genus are the large white butterfly (*P. brassica*, Linn.), the small white (*P. rapæ*), and the green veined white, *P. napi*. Mr. Stephens, however, added several others, which have been regarded by some writers as varieties only of the common kinds.

POPULUS (Linnaeus). A genus of very conspicuous forest trees, natives of Europe and North America, bearing diœcious flowers, and ranging with the *Amentaceæ*. Four species are natives of Britain, viz., the aspen, the hoary, the aspen, and the black poplars. The Lombardy is a favourite in ornamental plantations; the black Italian produces the best timber; they are all propagated by cuttings of either their young shoots or roots.

PORTLANDIA (Linnaeus). A genus of highly ornamental trees, natives of Jamaica. They belong to the fifth class and first order of sexual botany, and to the natural order *Rubiaceæ*. This plant, to grow well, requires a strong stove heat, and is well worth every care to bring it to a flowering state, as when in flower it is a magnificent object.

PORTUGAL LAUREL is the *Cerasus Lusitanica* of Linnaeus, a common shrubby plant, and propagated by seeds, which ripen in abundance upon old trees.

PORTULACÆÆ. A natural order containing ten genera and fifty-five species already described. The *Portulacæ* and its allies are succulent herbs or shrubs with fleshy, entire, alternate leaves, and usually destitute of stipules. The inflorescence is axillary or terminal, solitary, or in spikes or panicles; the calyx is free or only slightly adhering to the base of

the germen; the petals are exerted from the calyx or torus, in number five, more or less; the stamens are definite, exerted with the petals from the calyx or torus; the filaments are discrete, the anthers versatile and two-celled; the germen is superior, one to three-celled, and many-seeded; the style single, and the stigmas several-cleft. The *Portulacæ* is the only plant of any use, the generality being only weeds.

POTAMOGETON (Linnaeus). A genus of aquatic perennials, all indigenous to Britain, where they are known as pond-weed. The genus belongs to the natural order *Alismaceæ*. None are in cultivation.

POTENTILLA (Linnaeus). An extensive genus of herbaceous perennials, found everywhere over the whole mountainous surface of Europe. The flowers are rather pretty, and for the most part yellow or white, and from their character are ranged in *Rosaceæ*. They may be called ornamental weeds; though there are a few exotic species which deserve a place in the flower garden.

PRASOPHYLLUM (Dr. Brown). A rather numerous genus of tuberous-rooted herbs, natives of New Holland, belonging to *Orchideæ*. According to Sweet, they should be planted out in a frame in a mixture of light loam, sand, and peat earth, and only protected from frost.

PRAWN. A small crustaceous animal belonging to the long-tailed (*Mucronous*), ten-legged (*Decapodous*) division, and to the family *Palæmonidæ*, being, in fact, the typical species of that family, and known by the technical name of *Palæmon serratus*. It is highly prized as a delicate shell-fish. See *PALÆMONIDÆ*.

PREMNA (Linnaeus). A genus of tropical trees bearing didynamous flowers, and belonging to *Verbenaceæ*.

PRIMULACEÆ. A much admired natural order of mostly humble plants, comprising within its limits seventeen genera and one hundred and forty-three species. They inhabit the mountains and meadows of all parts of the world, but especially in the northern hemisphere. "Nothing can surpass the beauty of the little delicate Alpine *Primulas*, *Androsaces*, *Aretias*, and *Soldanellas*, with their modest blossoms sometimes rivaling the whiteness of the surrounding snow, and sometimes emulating the intense blue of the empyrean." They are as much valued for their early advent as for their intrinsic beauty; for no sooner is the snow melted, and the earth loosened by the vernal airs, than these harbingers of spring put forth their welcome blossoms. Besides the above named genera there is the *Cyclamen*, the elegant *Dodecatheon*, (considered worthy of being dedicated to twelve divinities), the *Cortusa*, *Trientalis*, *Coris*, *Huttmia*, *Lysimachia*, *Lubinia*, *Anagallis*, *Micranthemum*, *Cerastium*, *Samolus*, and *Campyloanthus*. The prominent botanical character of the order is the fruit, one-celled, with a central placenta, and the stamens opposite the petals. The properties of these plants are insignificant, nature having thus as it were secured some of her prettiest flowers from rapine, and spared us kindly the pain of destroying these most delicate specimens of her handiwork. The tubers of the *Cyclamen* abound in south-eastern Europe, and are eagerly devoured by swine; hence the plant is called sowbread. A kind of wine is made from the flowers of the cowslip, said to be useful in fevers. All the genera are increased by division or seeds.

PRINOS (Linnæus). A genus of North American evergreen shrubs, commonly called winter-berry. The flowers are hexandrous, and the genus belongs to *Rhamnaceæ*. The species grow in any light peaty soil, and are increased by layers.

PRIONIDÆ (Leach). A family of coleopterous insects, belonging to the section *Tetramera*, and sub-section *Longicornes*, distinguished by having the upper lip obsolete, the body generally of large size and depressed. The jaws often very large, especially in the males; the antennæ of moderate length, the thorax often denticulated at the sides. The family is of considerable extent, and comprises some of the most gigantic insects of the order to which it belongs; thus, *Prionus gigas* is six inches and a half in length, and *P. cervicornis* five inches and a half including the mandibles. They frequent the great forests of tropical climes in which the trees are old and of a large size, as it is in the wood of the latter that the larvæ reside. These larvæ do not materially differ from those of other beetles having similar habits; the head is small and the body thick, fleshy, and depressed, with the legs very minute. These larvæ are supposed by some authors to be the *Cossus* of the Romans; and it is certain that they are greedily devoured by the negroes in the West Indies. When they have attained their full growth they spin a cocoon of silk with chips of wood, within which they undergo their transformations. They take care to place this cocoon near the surface of the tree, so that the insect, when arrived at the imago state, may the more easily find its way to the open air. The females are provided with a corneous tubular borer, which they introduce into crevices in the bark in order to deposit their eggs. During the day they remain quiescent in the woods, but come forth in the twilight and fly round the trees. The family comprises the genera *Spondylus* and *Prionus*, which latter has recently been divided by M. Serville into a very great number of sub-genera. We possess in England but a single species *Prionus coriarius*, which is about an inch and a half in length, and of a dark brown colour. See *CERAMBYCIDÆ*.

PRISMATOCARPUS (Heritier). A genus of annuals and two or three perennials, natives of Europe and South Africa. The flowers are pentandrous, and the plants belong to *Campanulacææ*. The genus was long ranked as *Campanulas*, until separated by Heritier. The African species are treated as greenhouse plants, and the annual sorts as tender annuals; that is, raised from seed in a hotbed, and afterwards planted in the open borders.

PRIVET is the *Ligustrum vulgare* of Linnæus, a European shrub, much used in forming ornamental shrubberies. It belongs to *Oleaceæ*.

PROCTOTRUPIDÆ (Oxyura, Latreille). A family of hymenopterous insects of considerable extent, belonging to the sub-section *Pupivora*, having the wings almost destitute of nervures, the antennæ composed of from ten to fifteen joints, the abdomen terminated by a tubular ovipositor, and either external, forming a terminal point, or internal and exsertile. The maxillary palpi are generally long and slender. These insects are of minute size, and generally of a black colour, with pale or red legs. They are found in grass and amongst leaves, and generally are very active. From the *Chalcididæ* they differ in having the antennæ straight, and the nervures of the anterior wings often more conspicuous, whilst the structure of the abdomen and the ovipositor

distinguishes them from the *Cynipidæ* and *Ichneumonidæ*. This family has been recently investigated by Dr. Nees von Esenbeck, as well as by several English authors, by whom many species have been described, and numerous genera established. They are parasitic upon other insects. Some of the species exhibit various remarkable peculiarities. Thus the *Platygaster Boscii* is furnished with a long curved horn, which arises at the base of the abdomen, and extends over the thorax as far as the head. The species of *Galesus* are remarkable for having the mandibles elongated into a kind of beak, and the female *Gonatops* are provided with a curious pair of recurved pincers, attached to the fore tarsi, quite unlike any thing to be observed in any other insect. The wings of the *Duripræ* are entirely destitute of nerves, and the *Mymars* (including some of the most minute creatures belonging to the order, and visible only when creeping upon the window between the eye and the light) are provided with a brush of very long hairs upon the margins of the wings; whilst the genus *Proctotrupes* is distinguished by the exserted and conical ovipositor; the antennæ thirteen jointed, and straight.

PROMEROPS (*Epienachys*). A genus of birds belonging to the slender-billed family of *Passeres* in the arrangement of Cuvier. They have sometimes been confounded with the bee-eaters (*Merops*); but the structure of their feet, the form of their bills, and their modes of feeding, are quite different. The bee-eaters are syndactylic, or have the outer front toe and the middle one of equal length, and united together as far as the last joint, which makes that part of the foot in a great measure the same as one large toe with a cleft point. *Promerops*, on the other hand, are anisodactylic, having the middle and outer toes of different lengths, and united only at their bases. In this respect they resemble the nut-hatches, creepers, humming-birds, and hoopoes, to the last of which they have the closest resemblance. Their mode of feeding is different, however, for they live in a great measure upon the nectar of flowers, for the procuring of which their bills and tongues are well adapted.

The characters may be stated as follows:—The bill much longer than the head, slender, and with the gape opening as far backward as the eyes; the mandibles very much compressed, sharp in the edges for the whole of their length, the upper one very slightly notched toward the point, exceeding the under one in length, and with the crest on the culmen, which advances between the plumes and the forehead; the nostrils, at the base of the bill, opening forward, and in part covered by a feathered membrane; the tarsus of the same length as the middle toe; the outer toe longer than the inner one, and united to the middle one at its base, and the hind toe furnished with a very strong claw; the wings are of moderate length, and rounded, the first quill being very short, the next three gradually longer and longer, and the fifth one the longest in the wing. The natural history of these birds is not a little confused, as they have been differently viewed by different writers, and variously mixed up with other genera, with which it does not appear that they have much real connexion either in their geographical distribution or their habits. The most characteristic of them are understood to be natives of Southern Africa and Australia, of the islands which lie between them, and of some of the islands

eastward of New Holland; and the American species, which have sometimes been added to the genus, all belong to others, either to the sugar-eaters, or to some other genus nearly resembling them. In this uncertainty, we can do little more than mention the names of a few of the best-established species, remarking, that the whole are tree or plant birds, that their tongues are cleft at the extremity, and otherwise adapted for collecting those sweet juices from the nectaries of flowers upon which the birds may, in a great measure, be said to feed.

SPLENDID PROMEROPS (*E. splendens*). This is a very beautiful bird, a native of Australia, and between nine and ten inches in length. The upper parts, and the head, neck, and breast, are velvet black, with reflections of green and purple; the feathers on the sides are large, rounded at their extremities, and each marked with a spot of very rich golden green; the feathers on the flanks are yellowish white, produced, and having thread-like niches; and some of them have the shafts drawn out in long filaments; the middle coverts resemble the back, and the external ones are black, with red borders; all the under parts are white; the bill and feet are black. These birds inhabit the Australian forests, and are understood to suck the sweet juices of flowers, but their habits are very little known.

MAGNIFICENT PROMEROPS (*E. magnificus*). This is also a native of Australia, a larger bird than the species last mentioned, and still more brilliant in its colours. The upper part is black, with purple reflections, and the coverts of the wings pass into golden purple at the tip and margins; the quills, which are the same colour as the back, are very broad, and squared over at the ends; the middle tail-feathers are greenish-purple, and the lateral ones black; there is a sort of gorget of blue scaly feathers on the throat and fore neck, a collar of bronze-green below it; and the breast is glazed with silvery reflections; the under parts and flanks are iridescent violet, the feathers on the latter being long, and with loose backs, something resembling those of the birds of paradise; the bill and feet are black. The entire length is about twelve inches.

POINTED-TAILED PROMEROPS (*E. caudacutus*) is a native of the island of Madagascar, and about eleven inches in length; the upper part is black, with dull green reflections; the primary quills are black, the secondaries mottled with white and yellow in the central parts; and the tail-feathers, which are painted at the tips, are iridescent black; the lower parts are blackish brown; and the bill and feet are black, with a white streak on the ridge of the former.

HIBERN PROMEROPS (*E. sibilans*). This is a South African species, smaller than any of those already mentioned. The upper part is brown, clouded with olive; and the lower part white, passing into brown on the flanks, a collar of white surrounds the neck; the lateral tail-feathers are white, striated with brown and black; the bill is brown, and the feet yellow; the bird gets its name on account of the low humming noise which it makes while flying, but otherwise its manners are very little known.

AZURE PROMEROPS (*E. cyaneus*). This is also a South African species, and one of the largest of the whole, measuring not less than fourteen inches in length. The upper parts are azure blue, with green reflections; the quills and tail-feathers are silver grey on the outer part, with azure margins; the

under parts of the body are sky-blue, marked with green; the bill is blackish; and the feet bluish grey. This species is the Indian hoopoe of some authors, but they are wrong in both respects, as it is neither a hoopoe nor an Indian bird.

RED-BILLED PROMEROPS (*E. erythrorhynchus*). This is also African, and measures twelve inches in length, but the female bird is a little less than the male. The upper parts are bright shining green, with reflections of blue and bronze; the quills and lateral tail-feathers are spotted with white; the under parts are of a variable colour, green in some lights and violet in others; and the bill and feet are red.

NAMAQUA PROMEROPS (*E. cyanomelas*). This species, as its name imports, is found in the Namaqua country, a rich district of Southern Africa, near the conflux of the Great Orange river with the Atlantic. The forests of that country are particularly rich in birds, as well as in antelopes and other animals; but they cannot be explored without much difficulty and some danger. The present species of promerops is about ten inches long in the male bird. In that sex the upper parts are black, with metallic reflections; the under parts black, with brown; the tips of the outer tail-feathers are white; and the bill and feet black. The female is considerably smaller; she has the bill less arched, the reflections on the upper part fainter, and the under part much more inclining to brown.

These are the principal species which have hitherto been discovered of this very peculiar genus. It will be seen that all of them belong to the southern hemisphere, to Southern Africa, New Holland, and the adjacent islands. Some species have been described as being natives of the West India islands, and of various parts of tropical America, but those which have been so described are all birds of different genera, and, generally speaking, belong to the *Cominostris* family, and not to the slender-billed birds; and of course this difference in the structure of so essential an organ as the bill indicates a corresponding difference in the habits.

PROTEACEÆ, a natural order of highly ornamental evergreen shrubs or trees, chiefly natives of the Cape of Good Hope and New Holland. The order contains thirty-two genera, of which there are three hundred and seventy-five species already described. The leaves are simple, narrow, entire or serrated. The flowers generally grow in clusters, and are green, yellow, or red, sometimes surrounded by coloured bractæ, with dark hairy margins. The flowers are tetrandrous, with distinct anthers. The stigma undivided, and mostly oblique. The fruit is various, sometimes a single nut, or congregated in a kind of cone. The proteas of the Cape, and the Banksias, dryandras, and telopea of New Holland, are the finest plants of the order. They are propagated by cuttings and seeds.

PROTELES, a genus of carnivorous mammalia walking on the toes, and intermediate in structure and appearance between the hyænas and the gennets, but not strictly admitting of being classified with either. There is only one known species, a native of Southern Africa, which is a country containing many singular animals; and in that country it is popularly styled a hyæna, though it is not one in reality. Lalande was the first to discover it; and Cuvier pointed out its characters, styling it provisionally the hyæna civet, and the hyæna gennet. In

some respects however, it has stronger resemblances to the dog family, especially the foxes, than it has to the hyænas or the civets, though it stands very like the hyæna on its legs, the fore ones being considerably longer than the hind. At first sight it is not very unlike the young of the common hyæna; but its head is differently shaped, and its toes are different in number. Its head is slender and handsomely formed; and its muzzle, instead of being blunt, is elongated, like that of the civet, or still more like that of the fox. The teeth resemble a little those of the hyænas, but they are not quite so carnivorous. The ears are long, and thickly covered with short hair, resembling those of the striped hyæna; the nostrils are on the point of the muzzle, which is black, and very slightly covered with hair; the mustachios are long and bushy; the hair of the mane, which extends all the way from the head to the tail, and the tail itself, are covered with rough and shaggy hair, which is hard to the touch, and the individual hairs are annulated by alternate portions of black and white; the rest of the body is covered with woolly hair, interspersed with a few long and stiff hairs; the ground colour is white, washed with reddish grey, and covered by irregular lines of black on the sides; the legs are the same colour as the body, with cross bands of black, except the tarsi, which are black altogether. This is rather a handsome animal; but it is comparatively rare in Southern Africa, and little known even to the native inhabitants. In its habits it is strictly nocturnal; and hence it is rarely seen unless when its earth is found and it is dug out. It appears to be to a certain extent social; for as many as three have been dug out of the same earth; but whether they join in hunting their prey has not been ascertained; they are about the size of a shepherd's dog, and are disposed to fight, and erect their manes when they are annoyed. It does not appear, however, that they are vicious in their dispositions, or make any serious inroads upon the farm yards of the settlers. Their limited numbers, and their retiring habits, tend, however, to render their history very imperfect.

PROTEUS, a genus of batrachian reptiles, closely allied to the tritons and salamanders, and, as a living animal, a singular inhabitant of singular places. Only one species is known, and that one is very local, being confined to the eastern Alps, and to some very singular places among them. The lakes in the neighbourhood of Sittich, in Lower Carniola, are the places where it was first found by the Baron de Zais, a zealous observer of nature, and by him it was communicated to Laurenti and Seapali, who wrote the first scientific accounts of it. Some of the lakes in which it was observed, are of singular character; for part of the year they show an expanse of surface-water like other lakes; but at one season the whole of the water withdraws into a hole in the bottom, and the bed of the lake becomes a meadow for a time. Subsequent research has found the proteus in other waters than these lakes; but still they are all connected with the rocks, or are what may be called "grotto-waters;" and no living specimen has been met with, excepting in some part of the Eastern Alps, between Vienna and the Adriatic. In the early ages of the world it appears to have been much more numerous than it is now, though still in the same part of the world. Remains or impressions have been found in the schistous strata at Eningen, of larger size than the living animal, but so much resembling it as to

show that if they are not the same identical species, they are certainly the same genus.

Schroëber, of the Vienna museum, was the first who made proper dissections, and gave a detailed account of the anatomy of these singular creatures, since which time they have taken their proper place in the system, between the aquatic salamanders and the sirens.

The known species was named *Proteus anguinus*, by Laurenti, though some others improperly classed it among the sirens. It is an animal more than a foot in length, and about the thickness of one's finger, with the tail compressed vertically, and four rudimentary feet, with three toes on the fore feet, and two on the hind ones. Its feet are very badly developed, so that it walks slowly and badly; but it swims easily and rapidly after the manner of tritons. It is furnished with internal lungs and also with gills on each side, which latter are of a coral red colour, and appear to be used in breathing much more frequently than the lungs. The proteus is thus a truly amphibious animal, capable of breathing either dry air, or air through the medium of water. Its gills are in the form of three little tufts upon each side, and it does not appear to lose them at any period of its life, so that the name proteus, which means a changer, is very inaccurately applied to it. Its eyes are so exceedingly small, and so much covered by the integuments, which form a sort of pit around them, that they are hardly visible. The ears are also covered with flesh, and both these senses appear to be in a very low state of development. It very often happens, however, that when an animal has the localised senses so imperfect that we are apt to pity its helpless condition, the general sense of the body is so much increased, as completely to supply the defect of all the other senses. This seems to be particularly the case with this animal, for it is exceedingly impatient of light; and if exposed to a strong light for any length of time it dies. Its general colour is whitish, with a rosy tint in the living animal, but the bloom of this tint goes off after death. The original opinion, that it was the larva of some sort of salamander has been totally exploded; first, because there is no salamander in the places which this animal inhabits; and secondly, because the skeleton of the proteus, and its general organisation, are totally different from those of the salamander in every stage of their existence. The proteus has a sort of larynx and windpipe, and utters a feeble voice intermediate between hissing and whistling.

The skeleton bears some resemblance to that of the salamanders; but the vertebrae in the spinal column are more numerous, and the rudimentary ribs are fewer. The bones of the head more resemble those of the siren. There is no crest on the cranium, which is very much depressed. The bones of the nose are merely rudimentary; but the processes of the intermaxillary bones are long, and each of them is furnished with a row of teeth to the number of eight or ten. The vomers are also furnished with teeth more numerous than the inter-maxillaries, and extending far back into the mouth. The proper maxillary or jaw bones, and also the bones of the palate, are entirely wanting. The under part of the cranium is flat, formed by a single spheroid bone, but there are no walls or partitions of bone to the nostrils, which open into the mouth. The neck and body consist of thirty vertebrae, and the tail of twenty-five. With

the exception of the terminal one, these bones are very perfectly ossified; but their articulations to each other very much resemble those of fishes—that is to say, each of the two ends which are opposed to each other has a hollow cavity, and the two cavities are filled with cartilage. The ribs are seven on each side, and merely rudimental. There is no sternum, but there is a cartilaginous envelope to the heart, which in some sort answers the purpose of a sternum. The bones of the extremities are exceedingly imperfect, the blade-bone being the only part of the shoulder which is not cartilage, the bones of the pelvis being still less perfect, and those of the feet cartilaginous at their extremities. It appears that the animal has the power of sending a current of water from the mouth to the gills; for there are openings in the hinder part of the mouth which have their exit between the tufts of the gill. The liver consists of three lobes; the gall-bladder is very ample. The heart, which is situated between the fore feet, and whose cartilaginous envelope appears to assist in keeping them asunder, has but a single ventricle and auricle. The lungs are exceedingly simple, consisting of a few small and short tubes, a little dilated at their extremities. The stomach is thick and leathery; but the intestinal canal is slender. Small shelled mollusca appear to form part of the food of the proteus, as they have been found in the stomach; but the habits of the animal are so exceedingly obscure, that very little is known respecting them; and those which have been kept for a short time in confinement, have refused every kind of food. Of their mode of production nothing is known; and, indeed, the traces of organs for this purpose are very obscure.

Altogether this is one of the most singular animals in Europe; and its impatience of the light, and disposition to lurk in the sand, under stones, or in the darkness of subterranean waters, is greater than that of any other known animal. It also seems to be exceedingly sensitive and delicate, as no supply of water, no shading, and no treatment which has been hitherto resorted to, have succeeded in keeping it alive for any length of time.

Another species, almost equally obscure, and found in some parts of the United States, especially in New Jersey, has been referred to this genus, but apparently without propriety. It is a smaller animal, round in the body, with a groove down the back, having the tail flattened like an oar, and four little toes upon each of the feet. The accounts of it are, however, very vague.

PRUNELLA (Linnaeus). A genus of perennial herbs, natives of the northern parts of America and Europe. They have mostly didynamous purple flowers, and belong to *Labiata*. A few of them are admitted into the flower garden, but the majority are only useless weeds.

PRUNUS (Linnaeus). A genus of deciduous shrubs and trees, mostly natives of Britain and other parts of Europe. They belong to the class *Icosandria* of Linnaeus, and to the natural order *Rosaceæ*. The species are the wild sloes of our hedges, and the cultivated plums of our gardens.

PSELAPHIDÆ (Leach). A family of coleopterous insects, nearly allied to the rose beetles (*Brachelytra*), but having the tarsi only three-jointed. These curious little insects have attracted much attention from the singularity of their characters. The abdomen is short and oval or rounded, and partially

covered by a pair of short truncated elytra; the antennæ are thickened at the tips, sometimes only six-jointed, but more generally with eleven joints, some of which are curiously formed in one of the sexes; in some of the species the palpi are in general very long, and resemble an additional pair of antennæ; the tarsal joints are entire and slender, and often terminated by a single claw. These little insects are found in moss or amongst grass, at the roots, whilst others frequent ants' nests. The genera are *Pselaphus*, *Batrissus*, *Chennium*, *Dionyx*, *Bythinus*, *Arcopagus*, *Clemistes*, *Bryaxis*, *Tychus*, *Euplectes*, *Claviger*, and *Articerus*, the most remarkable of which have been noticed in their alphabetical situation.

The genus *Pselaphus*, in its restricted state, comprises only those species which have the maxillary palpi elbowed and as long as the antennæ, which latter are eleven-jointed; the tarsi are terminated by a single hook. There are several British species, the type being the *Pselaphus Heisei* of Herbst.

The monographs of Leach (*Zoolog. Miscell.* vol. 3), Reichenbach, and Aubé, must be consulted for the characters of the genera and species of this family.

PSIDIUM (Linnaeus). A genus of tropical forest trees, bearing icosandrous flowers, and belonging to the natural order *Myrtaceæ*. The fruit are the guavas of the colonists, some of which are equal in quality to our summer pears. The different sorts grow freely in our stoves and bear fruit, but they are not held in estimation so much as to be cultivated entirely for their fruit, as some other tropical fruits are. They are propagated by layers or cuttings.

PSOCIDÆ (Leach). A family of neuropterous insects, belonging to the section *Filicornes*, having the head not anteriorly produced into a rostrum; the first segment of the thorax very short; the second large and exposed; the wings deflexed at the sides, slightly reticulated, the posterior pair being the smallest; the tarsi are composed of two or three joints; the antennæ are setaceous and ten-jointed; the maxillary palpi exposed; the labial palpi indistinct. The family derives its name from the Greek, and signifies to pull to pieces, and is given to it in consequence of the habits of the larvæ, which, as well as the perfect insects, are found in old books, neglected collections of natural history, on old palings, under stones, &c. They are very active, running and flying quickly, and leaping out of the reach of danger. The larvæ resemble the perfect insects, both in habits and appearance; they are, however, unfurnished with wings, and unable to continue their kind; in the pupa state the wing covers are rudimental; the species are rather numerous, and of very small size. The type is the *Psocus quadripunctatus* (Fabricius), belonging to the typical genus *Psocus*; the other genus, *Atrypus*, is described in its place.

PSORALEA (Linnaeus). A genus of evergreen shrubs and herbs, mostly natives of Africa; they belong to *Leguminosæ*. They are all more or less ornamental, and one, the *P. esculenta*, having tuberous roots, is cultivated on the banks of the Missouri. It is the *Pomme de Prairie* of the Canadians, and affords, during winter, a nutritious farinaceous food. Several of the species are medicinal. They are easy of cultivation, and propagated by cuttings.

PSYCHE (Schrank). A very curious genus of lepidopterous insects, belonging to the family *Arctiidae* (Stephens), having the body slender; the antennæ of the male bipectinated, of the females simple: the former sex is provided with ample wings, of which the

atter is entirely destitute, being moreover of very small size compared with the males. The wings of the males are semi-transparent, being clothed with hair rather than scales, a peculiarity characteristic of the *Trichoptera*, with which order these insects are still more nearly allied by the habits of the larvæ, which reside in cases formed of bits of twigs, leaves, &c. woven with silk. The following observations, communicated by Mr. Ingpen to Mr. Stephens, will be read with interest, involving as they do a curious point in physiological entomology :—

"In June last I procured a considerable supply of both larvæ and pupæ of *Psyche fusca*, found at Hornsey Wood, upon the hazel, willow, &c., some only half the size of the others, from the largest of which I obtained four males and two females in the beginning of July; the larvæ in the smaller cases being still (Nov. 24) alive, from which I conceive that they remain at least two seasons, if not more, before they attain perfection, which opinion is strengthened by the fact of my taking the young larvæ*, on 17th July, 1827, under three-fourths of a line in length, including the case, which are now but four lines long, and which I fed at first on the leaves of the willow, the cuticle of which they devoured, and with the downy portion they formed their cases; during the winter they remained fixed to the upper part of the inverted glass in which they were placed (having made the sides easy of ascent by covering them with a fine silken web), and in March they began to stir, when I supplied them with the buds of whitethorn and afterwards with willow; they gradually increased the size of their cases, and added to them fine saw-dust and pieces of leaves, and after a few weeks they again became immovably fixed, and from each of them the chalcideous parasites mentioned in the note were produced, and their extremely slow growth not only indicates their anomalous longevity, but satisfactorily shows why they are so obnoxious to the attacks of the parasites. The females never leave their cases," hence, Mr. Stephens adds, "how the union of the sexes takes place it is difficult to imagine, as the female does not leave her birth place, and the extraordinary smallness of the latter sex is very remarkable."

The genus, as restricted by English authors, comprises only a single species *Psyche fusca* (Haworth), the male of which is three-quarters of an inch in expanse, whilst the female is only one-sixth of an inch long; the wings on the male are entirely pale brown. The French entomologists, however, introduce into the genus the numerous small species, composing the genus *Fumea* of Haworth, which differ only in the rounded form of the wings and the straight pectination of the antennæ.

PSYCHODA (Meigen). A genus of minute dipterous insects, belonging to the family *Tipulidæ* and subfamily *Culiciformes*, having the wings broad, lanceolate and deflexed at the sides when at rest, the legs placed at equal distances, and the antennæ composed of a series of globular joints. These little flies have the body, wings, and antennæ clothed with long hairs which, with the position of the wings when at rest and their large size, give to them the appearance of very small moths. They are found in damp places, and some of the species may often be seen on the

windows of our apartments. There are about a dozen species, the type being the *P. phalaenoides* of Latreille.

PSYLLIDÆ (Latreille). A family of homopterous insects, belonging to the division *Aphidians*, Latreille, having the antennæ composed of ten or eleven joints, the last being terminated by two setæ; the legs are formed for leaping; tarsi two-jointed. These are small active insects, found upon various vegetables upon which they form gall-like excrescences, by wounding the tender parts of the plants with their rostrum, for obtaining a supply of food. The larvæ have the body flat, the head large, and abdomen obtuse behind. The perfect insects are very active, and the females deposit their eggs in the midst of a mass of a white downy secretion. The family comprises three genera, *Psylla*, having the antennæ filiform, comprising numerous species (the type being the *Chermes buri*, Linnæus) and *Livia*, having the antennæ short and very thick, and *Levilla*, Curtis's Brit. Ent. pl. 625.

PTEROCARPUS (Linnæus). A genus of tropical trees, belonging to Linnæus's class *Monadelphica*, and to the natural order *Leguminosæ*. The species are treated as stove plants, and are easily increased by cuttings. *P. draco* is one of the trees which exude, when cut, a reddish sap, called dragon's blood. This resin was formerly exported in great quantities from Carthage; but, from diminished consumption of the drug, its collection has ceased; the produce of *Calamus draco* being now used as a substitute.

PTEROCERAS (Lamarck; *Strombus*, Linnæus). These molluscs have been separated from the Linnæan *Strombi*, in consequence of their not having the canal at their base shortened, or truncated, as is the case in the *Strombi*; it is, on the contrary, elongated in the form of a tail attenuated to its extremity, and generally closed in adult examples, the right margin dilated by age into an expanded *digitated* wing, attached to and covering the whole of the spire; the lower part interrupted by an interval or wide gap. This is not contiguous to the body of the shell (as in the *Rostellaria*), but distant and similar to that of the *Strombus*, which is only distinguished from this genus by the short canal and the want of digitations; we are therefore disposed to agree with the classification of Linnæus, particularly as a knowledge of the animal does not point out sufficient reason for separating it from the *Strombus*, which it closely resembles in all its organisation. Lamarck uses the term *digitations* generally for that portion of the shell which, in some species of this genus, may be more properly called claws, whence the trivial name of scorpion, or spider shell. In young molluscs of this genus these are not produced. The name given by Lamarck to this genus is derived from two Greek words, meaning a horn and a wing. Nearly all the species are inhabitants of the Indian ocean, and many of them exhibit the most beautiful colours on their lower or internal surface. Very few species are known in a fossil state. In Swainson's Exotic Conchology these molluscs are more faithfully and more exquisitely figured than in any other work extant.

PTEROMYS—Winged Mouse, or, more strictly speaking, Winged Squirrel. A very remarkable genus of rodent animals, formed, in some parts of their bodies, like the *petaurista*, or flying marsupial animals of Australia; but unlike them, and resembling the squirrels properly so called, in the structure of their teeth and in their general habits. They are furnished with large clavicles for their size, which gives a

* "Which larvæ, although taken so young, produced a great abundance of chalcideous parasites in June last, the eggs of which must either have been deposited in the young larvæ upon leaving the eggs or in the latter, if not introduced upon the leaves upon which they were nourished."

powerful cross motion to the fore legs, so that these can be thrown outwards nearly at right angles to the axis of the body. The hind legs also are capable of very wide motion. In their system of teeth, their organs of sense, their mode of reproduction, and, generally speaking, in all the essential parts of their organisation and habits, they are true squirrels: and the description of them thus far may be referred to the article *SQUIRREL*. There is even, in some of the other squirrels, a slight approximation to what forms the distinguishing character of the present genus: the bodies of these are flat, they can spread their feet wide, and the skin of their sides stretches a little near the fore legs and flanks to break their fall. In the present genus the skin is regularly extended from the fore legs to the hind ones, covered with thick and soft fur, and forming a most efficient parachute. There is also a particular bone attached to the foot for supporting this membrane; so that, though this peculiar formation cannot be said to originate any of the motions of the animals, it enables them to leap much farther from branch to branch than if they had no extensible skin on the sides. This alone entitles them to be considered as a distinct group, and as such they are a very well marked one.

We need not say that these animals do not fly, or that the word flying is inaccurately applied to them; for there is no instance of a vertebrated animal performing real flight by the motion of any other bones than those of its anterior extremities. These animals can no more take a second leap, or gain a fresh impulse from the air as a fulcrum, than the heaviest of the mammalia; they can merely leap to a great distance, and it is this which is their habit in enabling them to pass from tree to tree, over considerable openings in the forest, without descending to the ground. We need not add that they are forest animals, because the apparatus with which they are furnished would be an incumbrance to an animal in any other locality. They are not found in the wooded countries of all parts of the world, but they range considerably in latitude, being found in polar countries, and also in tropical ones. They are met with in the woods of Canada and the United States, though not in the tropical or southern parts of America. Some of them occur in Lapland, and along the northern forests of the eastern continent, as far as the eastern part of Siberia. They are met with again in India, and in Java and some other of the eastern islands; but in Australia their place is occupied by those marsupial animals with laterally extended skin to which we have alluded.

Some naturalists have divided them into two sections or subgenera, according as they have the tail round, or broad and flat like that of the squirrel. The name *Pteromys* has been restricted to those with the round tails, from that being the form of the tail in a mouse; and those with the flat tails have been called *Sciuropterus*, or flying squirrels. The two divisions are pretty distinct from each other, both in this character of the tail, and in the nature of the places where they inhabit. Those with the round tails are larger and more handsome animals than those with the flat; and they are met with only in the warmer parts of America, and in the Asiatic islands; the flat-tailed ones are smaller, less handsome, and chiefly, if not exclusively, found in cold countries.

PRONOTUS. The tails in these are round, and

the hairs do not stand out distinctly from each other. There are several species; but the nature of their haunts, and the rapidity with which they make their way among the thick branches of the trees, leaping fearlessly and smoothly where they cannot run, renders the study of their habits very difficult, and the consequence is that but little is known concerning them.

P. petaurista. This is the sailing squirrel, and also the great flying squirrel of the oriental isles. In the native language of the Malays it is termed *Jaguar*. The upper part of its body is brown, mottled with white; the under part greyish white, and the under side of the tail more or less brown, though above it is black for nearly the whole of its length; the thighs are red, and the feet brown; the borders of the mouth and around the eyes are blackish, the mustachios are black, and the cheeks and top of the head are mottled brown and white. The flying membranes form salient angles at the wrists, and there is a small rudiment of a membrane at each side of the base of the tail, united to the insides of the thighs, preventing the escape of the air in that way when the animal leaps. This is rather a large animal for the family to which it belongs, the head and body being about a foot and a half long, and the tail nearly one foot nine inches. It is understood that the habits of this animal are nocturnal, but very little is known of them. It occurs in the Molucca islands, the Philippine, and various other groups in the Eastern seas.

P. nitidus—the bright flying squirrel. This species inhabits the same part of the world as the former, though perhaps a little more to the westward, being more numerous in Java than in the isles further to the east. Its form and size are very similar to those of the preceding species, only it is, generally speaking, an inch or two shorter. Its colours are different, which makes its chief distinction, for its manners are just as little known as the other. The upper part is dark brown, and the under bright red. The tail is the same red as the under part at its base, but gets deeper toward the extremities. It is probable that this one is subject to some varieties of colour, because specimens have been met with agreeing with it in all their other characters, but having the belly white. There are some other species in the oriental islands, but they appear to belong to the flat-tailed section.

SCIUROPTERUS. The animals of this section have the teeth exactly like the common squirrels, while those of the former section have them different. In that section the teeth are simple teeth, without showing any layers of cortical matter, alternating with enamel in the crowns; and of course they indicate a difference in feeding, though it is not known in what the difference consists. The present section, which have cheek teeth like the squirrels, must of course be understood to feed upon the same substances and in the same manner as squirrels do.

S. sajitta. This species is found in Java and the adjoining islands, and differs from those of the former section in size, as well as in the structure of the teeth and in the form of the tail. It is only five or six inches long in the head and body, and nearly the same in the tail. Its prevailing colours are brown on the upper part, and white on the under. The lateral membrane forms a sharp salient angle behind the rest, the same as in the animals of the former genus.

S. genibarbis, called Kechubu in Java, is about the

same size as the preceding, and the chief difference between them consists in the colour, the upper part being grey, the under part whitish, and there are long stiff hairs on the cheeks and sides of the head, which appear to serve as organs of touch in the living animal.

S. Sibericus, the common flying squirrel, is a native of the forests in the colder parts of Europe and Asia. Its residence is in the pine forests, and it is not rare in Sweden, Finland, the wooded tracts to the east of the Baltic, and so on eastward through Russia and Siberia. Its colours are ashey grey on the upper part and white on the under; its tail is broad, and only about half the length of the body; and the lateral membrane, instead of forming a sharp angle behind the rest, forms a simple lobe. It jumps with great alacrity, and very seldom misses its hold or falls to the ground; it is a lively little animal, and far from being the least interesting inhabitant of those dreary forests in which it resides. It has sometimes been confounded with the North American species, but they are perfectly distinct. In Cuvier's arrangement it is very properly taken as the typical animal of the sub-division. The name given to it by the Russians, who capture it in great numbers as a fur animal, is *polatucca*, which name was Frenchified by Buffon, and applied to the American species.

S. volucella. This is the American one, found abundantly in the wooded parts of the United States, where the animals associate in little companies, and give much liveliness when they are put in motion. They live upon fruits, seeds, and the buds of plants. It is a very small animal, not above five inches long in the body, or two and a half in the tail. Its colours are reddish grey above and white below. It is a lively little animal when in motion, but its chief time for activity is during the night. When kept in a cage it generally sleeps at the bottom during the day, but skips and frisks about with restless activity after night begins to set in. It does not appear that America contains any more than this one species.

PTERONIA (Linnæus). A genus of evergreen shrubs, found at the Cape of Good Hope. The flowers are syngenesious, and belong to *Compositæ*. They are easily managed greenhouse plants.

PTEROPHORIDÆ (PTEROPHORITES, Latreille; ALUCITIDÆ, Leach). A family of small nocturnal lepidopterous insects, distinguished from all other lepidopterous insects, by having the four wings, or two at least, slit longitudinally from the extremity to the base, and resembling branches or fingers, and deeply fringed, so as to have the appearance of feathers, whence these insects have obtained the names of plume moths. Their caterpillars are sixteen-legged; they feed upon leaves of various plants, and do not construct cases, like some of the *Tineidæ*. The body of the perfect insect is long and narrow, and their legs very long, so that many of the species (composing the genus *Pterophorus*) have so much the appearance of *Tipulæ*, that De Geer called them *Phalenes-tipulæ*. The genera are *Agdistes*, *Pterophorus*, and *Orneodes* (or *Alucita*). In the first, consisting of a single species, the wings are entire, but the whole appearance of the insect of which it is composed is so similar to that of the true *Pterophori*, that it must evidently be placed in the family. In *Pterophorus* (*Alucita pentadactyla*, Linnæus, &c.) the upper wings are divided into two branches, and the posterior into three; whilst in *Orneodes* (*Alucita*

hexadactyla, Linnæus), the wings are divided into six feathers.

PTEROPODA is the second family of the third order *Cyclobranchiata* of modern malacologists. It includes the genera *Atalanta*, *Spiratella*, and the never-to-be-determined inhabitant of the ARGONAUTA. See that article. The name of this genus is derived from an aliform appendage on each side of the animal's body, assisting its natation after the fashion of oars. The shells themselves are always symmetrical, extremely thin, semi-transparent, and longitudinally rolled from the apex forward, the evolutions being on the same plane.

PTEROSTYLIS (Dr. Brown). A genus of New Holland *Orchidææ*, introduced into our collections within these last twenty-five years. They succeed best in a frame, and in peat earthy soil, requiring only to be protected from frost.

PTEROTRACHEA (Lamarck). A naked mollusc, inhabiting the seas of hot climates. This genus at present only contains marine carnivorous molluscs, described by Semur, and it is not by any means sufficiently well defined to follow his arrangement without a further knowledge of them.

PTINIDÆ (Leach). A family of coleopterous insects, belonging to the section *Pentamera* and sub-section *Serricornes*, having the antennæ nine or eleven-jointed, sometimes pectinated or serrated, or in some species terminated by three large joints, not forming a solid club. The mandibles are short and triangular, the head short and rounded, or nearly globose, and hidden from above by the thorax, which is high and hood-like; the body is generally ovoid-cylindrical, convex above, and of a solid consistence.

The genera of which this family is composed are—

1. Antennæ uniform and simple. *Ptinus*, *Gibbium*, and *Mezium*.
2. Antennæ uniform, pectinated, or strongly serrated. *Ptilinus*, *Xyletinus*, and *Ochina*.
3. Antennæ terminated by three large joints. *Dorcatoma*, *Anobium*, and *Dryophilus*.

These insects reside in old wooden erections or furniture, upon which the larvæ feed, boring through them in circular holes. These larvæ very nearly resemble those of the *Scarabæidæ*, the body being fleshy and curved; they construct a cocoon with the fragments of wood which they have been gnawing, and therein undergo their transformations. The perfect insects counterfeit death, when alarmed, by lowering the head, withdrawing the legs and antennæ, and falling to the earth. Their ordinary movements are slow, and they seldom make use of their wings. The best known genus is that of *Anobium*, which comprises the insects commonly named the DEATH-WATCH (which see).

The genus *Ptinus* is distinguished from the other genera with simple antennæ, by the ovoid-cylindrical form of the body, and the insertion of the antennæ between the eyes. There are eight or nine British species, all of which are of small size.

PULEX (Linnæus). A genus (or rather *PULCIDÆ*, a family) of apterous insects, forming the order *Aphanaptera* of Kirby (*Siphonaptera*, Latreille), consisting of the various species of fleas. It is certainly a circumstance of some singularity that the three troublesome genera, *Pediculus*, *Cimex*, and *Pulex*, consisting of the lice, bug, and flea, should, both in a natural-history point of view, and with reference to their peculiar organisations, and consequent classifi-

cation, have proved perfect stumbling-blocks to philosophical entomologists. The peculiarities connected with the first of these groups we have sufficiently noticed in page sixty-three of the present volume; whilst the apterous condition of the second, in an extensive group of animals which are almost invariably winged, or at least wing-cased, is not without interest; and we have now to direct our attention to the flea. We take it for granted that some, perhaps many of our readers, will smile at our folly, as they will perhaps term it, in investigating the structure, history, and classificational station of the flea; but, as it happens that a knowledge of the structure, history, and classificational station of every animal is required to enable us to perfect our views of natural history; and as it also happens, as above remarked, that the flea is one of those anomalous creatures which, in all these points of view, have much perplexed entomologists, our enquiries may not, perhaps, after all, be so absurd as they might at first appear.

The Flea (*Pulex irritans*).

The body of these insects is of small size, of a hard shining integument, clothed with sharp bristles, arranged in transverse series upon the back and on the legs. It is very much compressed and apterous; rudiments of wings and wing-cases exist in the shape of two flattened plates on each side of the body above the posterior legs; the head is small; the mouth in the form of a rostellum, consisting of the six ordinary parts of an elongated form, and provided at the base with a pair of articulated organs, which have been regarded as antennæ, but which are in fact the maxillary palpi; the true antennæ are of minute size, and inserted in a cavity on the side of the head which is ordinarily closed by a moveable valve; the basal joint of the fore legs is horizontal, and extends beneath the head, so that the fore legs appear to arise from the head; the legs are strong, and formed for leaping to a very great distance; the tarsi are five-jointed, and terminated by two large hooks.

We are indebted to Messrs. Kirby, Curtis, and Duges, for valuable dissections of the various essential organs of the flea, which, previously thereto, had not been satisfactorily ascertained; consequently, as palpi were regarded as antennæ, antennæ overlooked, &c., it is no wonder that views concerning these insects and their relations should have been imperfect.

Of the history of these insects, in their perfect state, we need not say much. Every one has probably, at one time or other, suffered from their bites, and felt, at the same time, the impossibility of securing the little tormentor, which "comme l'amour, rit en sûreté de la blessure qu'elle a faite et de la colère qu'elle occasionne." But the flea does not always escape, nor is it always regarded with disgust. "Dear Miss," said a lively old lady to a friend of

mine (who had the misfortune to be confined to her bed by a broken limb, and was complaining that the fleas tormented her), "dout you like fleas? Well, I think they are the prettiest little merry things in the world. I never saw a dull flea in all my life.*" M. Bertolotto, the flea exhibitor, must be a man of infinite patience to train his regiment of fleas as he has done, producing an exhibition in which a first-rate man of war, of 120 guns, with rigging, sails, anchor, and every thing requisite in a three-decker, not omitting a numerous crew, placed on a car of gold with four wheels, are drawn by a single flea. A four-wheeled carriage, on springs, with four persons inside, the coachman on the box, and a footman behind, is drawn by a single flea. A gold chain of two hundred links, with a golden ball at the extremity, is drawn by another flea. Fleas, with golden saddles, bridles, &c., carry figures of proportionable size, representing Buonaparte and one of his aids-de-camp. Another flea draws up and lets down a bucket from a well; and two others fight a duel. There is, moreover, a representation of the siege of Antwerp, in which the fort is attacked by fleas with fire-arms and cannon, the explosion being heard by the visitors, and General Chassé and Marshal Gerard appearing on horseback, or, more properly, on fleaback, which is succeeded by a grand ballet, in which four of the performers (fleas), dressed in male and female attire, dance a quadrille to the music of a band of fleas playing on different instruments, of which the tones are audible to the company, and which is again succeeded by a representation of his Majesty's stag-hunt, the stag and his pursuers being personified by fleas.

Many of the readers of popular works on natural history will know that some of the feats performed by M. Bertolotto's fleas are not new, and that similar kinds of exhibitions have from time to time been made with the flea; but it is not every reader who is aware that the flea undergoes a series of transformations as great as those of the butterfly or the bee. On opening the body of a female flea ten or a dozen oblong eggs, of a rounded form and white colour, are discovered, which are deposited by the female in obscure places, such as cracks in the floor, or amongst the hairs of rugs, where dogs are accustomed to lie. From these eggs are hatched long worm-like grubs, which twist about in all directions, and which, having attained their full growth, form for themselves silken cocoons, when they become incomplete inactive pupæ, having the rudiments of all the limbs of the future insect visible. These larvæ are supposed to feed upon drops of congealed blood, which may be found lying with the eggs. Such, at least, is the opinion of M. De France, who has published a Memoir upon this subject in the first volume of the "Annales des Sciences Naturelles;" but this part of the history of the flea is certainly not clearly ascertained. This author collected some eggs on the 28th of August; on the 9th September they began to form their cocoons; and in sixteen more days they appeared in their perfect state. Thus we see there is no ground for the old notion, which Mouffet entertained, that the flea is produced from the dust, especially when moistened with urine, the smallest ones springing from putrid matter; or that recorded by Scaliger, that they are produced from the moistened

* Introduction to Entomology, vol. I, p. 102.

humour of dogs. It is certain, however, that the name given to the insect by the Romans, *Pulex*, is stated by Isidorus to have been derived from *pulvis*, dust, "quasi pulveris filius." It is to Leuwenhoeck and Rosel that we are indebted for a complete refutation of these fancies, these authors having first succeeded in rearing the insect through all its stages.

Having arrived at their final state, they commence their attacks upon us, or upon our animals, as well as upon pigeons, fowls, swallows, &c. They are very tormenting to dogs, cats, &c. The customary idea of sending dogs into the water to get rid of their tormentors is quite erroneous, as it has been ascertained, by M. De France, that fleas which had been kept under water for twenty-two hours had survived. Various plans have been suggested for destroying them, but there is nothing like water, soap, and the housewife's broom.

It is admitted on all hands that these insects, on account of their peculiar structure and transformations, constitute a distinct order amongst the metamorphic insects. Fabricius, indeed, regarded them as belonging to his order *Rhyngota*, containing the suctorial *Hemiptera*; and it was long thought that they were very nearly allied to the bug in the formation of the mouth. In their transformations, however, they are much nearer to the *Diptera*. De Geer formed them into an order which he called *Suctorica*. Latreille named the order *Siphonaptera*, Kirby *Aphanaptera*, and Lamarck restricted the name *Aptera* for their reception. By Latreille they are placed between the *Pediculi* (order *Anoptera*) and the *Coleoptera*. The diversity in these views, and the celebrated men by whom they have been entertained, will be sufficient to show the interest which attaches to this group of insects.

We have already given, in the article CHIGRE, an account of an insect of this family of a very obnoxious nature, namely, the *Pulex (Sarcophaga) penetrans*. Since our article was published, we have seen a translation of Messrs Pohl and Kollar's account of the same insect, published in the Magazine of Natural History, and accompanied by various figures; but it still appears that there are many important questions in the history of that insect which remain to be investigated.

Of the other species of the family, *P. irritans*, or common bed-flea, and the *P. canis*, or dog-flea, are best known. Some of the other species are remarkable for having the antennæ protruded from the lateral aperture of the head, and standing erect like a rabbit's ears. Mr. Curtis has formed these species into a genus named *Ceratophyllus*.

PULMOBRANCHIATA. The first order of the second class *Paracephalophora* of modern malacologists. Molluscs of this order have their organs of respiration retiform or aerial, lining the upper part of the cavity obliquely situated from left to right on the origin of the animal's back, and communicating with the ambient fluid by a small round orifice pierced on the right side of the reflected edge of the mantle. All the molluscs of this order are more or less capable of respiring atmospheric air; the greater number of them are terrestrial; some exist on the banks of fresh water, and sometimes on the border of the sea, none of them ever bury themselves in the mud, being incapable of existing long without a supply of air, except such as hibernate during the winter season, viz., snails and their congeners, they are all phyto-

phagous or vegetable feeders, and abound in all climates and portions of the globe. The first family *Lymnaea*, includes the genera *Lymnaea*, *Physa*, and *Planorbis*; the second family *Auriculacea*, a portion of the Linnæan genus *Voluta*, and the genera *Pedipes*, *Auricula*, and *Pyramidella*; the third family consists of the genera *Helix*, *Succinea*, *Bulinus*, *Achatina*, *Clausilia*, *Puppa*, *Caracalla*, *Helicella*, *Helicolumax*, *Testacella*, *Purmacella*, *Limacella*, *Limax*, and *Onchidium*. The species of this order are extremely numerous, many of them exhibiting the most brilliant tone of colours combined with the greatest delicacy of marking; and our common field-snail, the *Helix nemoralis*, may be quoted as an instance of an European mollusc vying in beauty with any of oriental origin, a circumstance rarely exhibited in shells of these northern latitudes. The facility which many species of this order affords the naturalist of consulting and examining the structure of testaceous molluscs renders them peculiarly interesting, and the animal organisation is so marvellous, that every young malacologist should patiently watch the development and habits of the snail, in which he will find many difficult solutions of Nature's operations more readily understood than the most able writer could explain; by this humble preceptor he cannot for one instant be led astray in drawing false conclusions as to the structure of all testaceous molluscs, and more particularly such as are univalve shells. Under the article CONCHOLOGY this fact is more amply detailed, we will not, therefore, longer dwell upon it, merely acknowledging our own gratitude for the instruction and delight we have derived from this source.

PULMONARIA (Linnæus). A genus of North American and European herbaceous perennials, bearing pentandrous purple, blue, or white flowers, and belonging to *Boraginæ*. These hardy plants grow on any light garden soil, and are known as lung-worts from the speckled appearance of their leaves. Several of them were formerly known as *Lithospermums*.

PULTENÆA (Smith). A genus of greenhouse or conservatory evergreen shrubs, natives of New Holland. The flowers are decandrous, and the genus ranks among the *Leguminosæ*. The species, which are pretty numerous (above forty), thrive well in loam and heath-mould, and are increased by cuttings.

PUNICA (Willdenow). A genus of two shrubs or small trees, bearing beautiful icosandrous flowers, and belonging to and constituting the order *Gramineæ*. Of one of the species *P. granatum*, there are three varieties differing in the colour and fulness of the flowers. See POMEGRANATE.

PUPA. One of the states through which the metamorphic insects pass immediately preceding that of the imago or perfect form. See the article INSECT.

PUPIPARA. A group of dipterous insects, which do not bring forth their offspring until it has attained the pupa state. See HYPOBOSCA.

PUPIVORA. A section of hymenopterous insects, which are parasitic upon other insects, which they generally destroy in the pupa state. See HYMENOPTERA.

PUPPA (Lamarck; Turbo, Linnæus). This genus of molluscs has very properly been separated from the *Turbinæ* of the Linnæan school, from which and the *Helices* this family is perfectly distinct; they

more nearly approximate the genus *Clausilia*, with which it properly should be united, as the animal is now ascertained to be precisely similar in its organisation. Shells of this genus are mostly terrestrial, few of them attain a large size, and many of them are quite minute; their form is cylindrical, generally thick, aperture irregular, half ovate, rounded, and sub-angular at the lower part; the margins nearly equal, reflected outwards, and separated at the upper part by a thin columella lip; the whorls at both extremities nearly of an equal size, while those of the body are larger and more ventricose. Some inhabit America, but the greater portion hitherto described are natives of Europe, many must also exist in India and Africa not yet enumerated by naturalists. Only one species in a fossil state is mentioned by De France.

PURPURA (Lamarck; *Buccinum*, Linnæus). This genus was blended by Linnæus with the genus *Buccinum*; it is the last in Lamarck's arrangement of that confused mass which presents the appearance of a canal at the base of the aperture, it consequently leads in order of proximity to the genera *Monodon*, *Concholepas*, *Harpa*, *Dolium*, *Buccinum*, &c., in all of which the canal has quite disappeared, and a notch merely remains. The gradual diminution of the canal, till it became altogether obsolete, probably occasioned Linnæus to arrange some of the species with the *Murices*, and others with the *Buccina*; there are, however, characters which distinctly mark this genus, and render it necessary to separate the molluscs composing it from the arrangement of previous authors. The aperture is never narrowed in the middle, either by plaits on the columella, or by teeth on the right side, but is always dilated; the columella is smooth, flattened, and terminating in a point at the base, where the notch is more or less obliquely placed, and appears a little ascendant backwards. The form of the shell is oval, either smooth or tuberculated, or angular on the exterior surface; the aperture ovate, dilated, sometimes internally grooved and slightly crenated or dentated at or near the right margin which is sharp. It has a semi-lunar shaped thin, horny operculum. The species of this genus probably amount to sixty, a few only of which inhabit the northern seas. The animals of many of these molluscs secrete a fluid which possesses a purple-tinged colour, but one in particular furnished that celebrated and costly dye of antiquity, called the Tyrian purple, now superseded by vegetable and mineral matter, at a price within the reach of every one, and not inferior in lustre.

PYCNOGONUM (Müller). A genus of marine aquatic arachnida belonging to the order *Podosomata* of Leach (see *ARACHNIDA*) having the legs as short as the body, and robust, the antennæ and palpi obsolete. They are parasitic upon the cetacea, the type *P. balænarum* being about three-quarters of an inch long, and of a whitish colour (see *NYMPHON*). Both in respect to their general appearance and parasitic habits this genus is very analogous to that of *CYAMUS* (which see).

PYRALIDÆ (Leach). A very extensive family of small lepidopterous insects, belonging to the section *Nocturna*, and having the antennæ setaceous, and but very seldom pectinated; the palpi two, recurved, or four; the thorax not crested; the body long and slender; the wings placed in a triangle in repose, the anterior pair being rather elongate and

glossy. There is considerable diversity of appearance in these moths, which were united together with the *Tortricidæ* by Latreille; and some of these species, including the type *Pyraha rostralis*, Linnæus (forming the genus *Hypena* of Schrank), are of considerable size, being more than an inch in expanse, but the majority are of a smaller size. They are in general active on the wing. The larvæ have fourteen or sixteen legs, those, at the extremity of the body never being deficient; they are naked, or have only a few scattered hairs. They often reside in a rolled up leaf in which, having first closed up the mouth, they change to pupæ. Mr. Stephens has established nearly thirty genera in this family, in his *Illustrations of British Entomology*.

PYRAMIDELLA (Lamarck; *Trochus*, Linnæus). This mollusc has been separated from the genus *Trochus*, to which Linnæus united it, principally because Lamarck supposed it a terrestrial species. The animal is, however, undescribed, and there appears no strong ground for supposing it other than a marine inhabitant. The shell is subconical, turreted without an epidermis; aperture semioval entire, and the outer lip sharp, the lower part of the columella a little projecting and sub-perforated at the base, with three transverse plaits; the umbilicus enlarged; about five living species are known, which are said to inhabit the Indian and American seas. Several fossil species are known, all from formations posterior to that of the chalk.

PYRETHRUM (Smith). A numerous genus of annual, biennial, and perennial herbs and shrubs, mostly European. The flowers are syngenesious, and belong to *Compositæ*. The shrubby species are green-house plants, and desirable as flowering in winter; the herbaceous sorts, commonly called feverfew, grow any where in the open ground.

PYROCHROIDÆ (Leach). A family of heteromerous insects of small extent, belonging to the section *Trachelides*, having the body narrowed in front and depressed, the thorax orbicular or trapezoidal. The antennæ, in the males at least, are pectinated, the maxillary palpi somewhat serrated, and terminated by a hatchet-shaped joint; the abdomen is elongated, and entirely covered by the elytra, which are rounded behind. These insects are gaily coloured, and are found in the spring months in hedges, &c. The larvæ reside under the bark of trees. That of *Pyrochroa coccinea* has been recently described and figured in the *Revue Entomologique de Silbermann*. The family comprises only two genera, *Pyrochroa*, Geoffroy, and *Dendroides*, Latreille, the first of which is British, and is distinguished by the antennæ of the males being simply pectinated, the eyes apart, and the thorax sub-orbicular. There are two handsome British species, *Pyrochroa rubens*, a very common species, of a fine red colour, and *P. coccinea*, of a bright red, with a black head.

PYROSOMA. A very singular naked mollusc, whose discovery is due to M. Lesueur; it inhabits the Mediterranean and Atlantic seas; three species are known.

PYRULA (Lamarck; *Murex*, Linnæus). The molluscs constituting this genus, as well as many other of different genera, were confounded by Linnæus with the genus *Murex*, in the classification of which he appears to have included all the shells having a canal at the base, rendering it an extremely incorrect and widely-extended genus. Bruguière,

who separated them the first, was only guided by the want of varices, and he did not distinguish the pyrula from the fusus, from which it widely differs; the spire of the former being short and very much depressed, and the last whorl extremely large and ventricose, frequently extending at its margin above the elevated point of the spire, and giving the shells of this genus the form of a fig or pear, which never occurs with the genus fusus. The pyrulae are in shape subpyriform, channelled at the base, without varices; columella smooth, and without a notch at the lip, to which may be added, that the edge of the aperture is most generally crenulated. The substance of this shell is very thin, semi-transparent, and with internal and external slight transverse ribs, interrupted by the sutures formed at the previous stages of the growth of the opening; they possess most of them a very wide umbilicus, and the aperture is closed by an ovate pear-shaped horny operculum. The animal is at present undescribed. About twenty-eight species are known, in a recent state, only one or two of which inhabit the Northern seas. Some fossil species are described.

PYRUS (Linnæus). A genus of ornamental and fruit-trees, the latter forming the chief of our orchard fruit, viz. the pear and apple. The service, white-beam, medlar, Siberian crab, &c., all belong to this genus, and to the natural order *Rosaceæ*. The varieties of these different species are most valuable, and are propagated by grafting on the common wild crab, or on their own seedlings.

PYURA (Molina). A species of *Ascidea*, evidently forming the connecting link in malacology between the simple and aggregated *Ascidæe*.

QUADRUMANA. Animals having the extremities of all their limbs formed like hands, including apes, baboons, monkeys, and a few others, for which see those articles, and the general article *MAMMALIA*.

QUARTZ. There are few mineral productions more beautiful or diversified than rock crystal or quartz. It is of great specific gravity, and its hardness fits it for the most enduring labours of man. It is frequently milk white, and of a more or less granular texture. The Sugar-Loaf Mountains near Dublin, the Paps of Jura in Argyshire, and some of the mountains of Sutherland and Caithness present well-marked instances of this geological formation. Brown and yellow crystals of quartz are found in great beauty in the mountains of Cairn Gorm in Scotland, and are much admired by the jewellers: they are sometimes called topazes. The purple quartz owes its beautiful colour to the presence of a little iron and manganese, and the rose quartz to the action of manganese alone.

QUASSIA (Willdenow). A South American tree having diandrous flowers, and belonging to the natural order *Simarubaceæ*. The generic name commemorates a negro of that name, who first used the bark as a medicine, and administered it with success in the treatment of malignant fevers endemic to Surinam. Quassia bark is sometimes surreptitiously used instead of hops, but a penalty attaches to the public brewer who uses it. It is neither so pleasant in beer, nor will the beer keep so well as if made of hops.

QUEEN BEE. The name usually given to the only fully developed female insect in the community

of the hive, all the other inhabitants being either males, or drones, i. e. females, whose development has been rendered partially abortive by reason of a certain peculiarity of food. See the article *BEE*.

QUERCUS (Linnæus). Of all hardy forest trees this genus is perhaps the most interesting as well for ship and other building, as for its grandeur in landscape and value of its fruit as pannage. The oak bears monœcious flowers, and belongs to the natural order *Amentaceæ*. There are already described sixty-two species and above twenty varieties, all natives of Europe and America. Some of them are shrubs, but the great majority are useful timber-trees, and at the same time highly ornamental. They are all propagated by seed when they can be procured, though some of the choice American kinds are increased by engrafting on the common British oak. There are two species (or one species and one variety) in the native woods of Britain; and it is somewhat remarkable that it is not yet (1837) clearly ascertained which of the two is the true naval oak of this country. The botanical difference between the *Q. robur* of Linnæus and the *Q. pedunculata* of Willdenow, is the circumstance (perhaps accidental) of the latter bearing its acorns on footstalks, while the former has its acorns sessile, that is, sitting close upon the bearing twigs. The *pedunculata* is a more elegant and freer growing tree; but the *robur* or sessile fruited has more the tufted and picturesque character of the British oak. That the timber of one of these is superior in durability to the other is well known to builders, but the best of the two has not yet been identified; some being of one opinion, and others of another. The authority of mere botanists is of no value in this question; and from the evidence of an eminent builder, Mr. Atkinson, it appears that the *Q. robur* yields the superior timber. This is a question of the greatest importance to nurserymen who raise seedlings for sale.

Besides timber, the bark is most valuable for tanning leather and cordage. The *Q. ruber* yields the material for the manufacture of corks; the *Q. tinctoria* supplies the quercitron, and the *Q. coccifera* the galls for dying.

QUINCE is the fruit of the *Cydonia vulgaris* of Tournefort. A common orchard fruit used by the cook and confectioner.

QUINOA. The specific name of a *Chenopodium* indigenous and cultivated in Peru for its seeds, which are used in that country as millet is in Europe. It has been introduced here as an economical plant, but does not answer.

QUISQUALIS (Linnæus). A genus of climbing shrubs, natives of Africa and the East Indies. The flowers are decandrous, and the genus belongs to *Combretaceæ*. The species (except *Q. indica*) are not much known in our collections; but they seem to be easy of culture, striking root readily by cuttings.

QUIVISIA (Cavanille). A pretty genus belonging to *Meliaceæ*. It is a stove plant introduced from the Isle of France, and succeeds well in heath-mould and sand, and in which soil cuttings strike roots freely.

RACCOON (*Procyon*). A genus of plantigrade carnivorous mammalia, having some resemblance to the bears, but still sufficiently distinct for being regarded as a separate genus. Their cheek-teeth are

six in each side of each jaw, the three posterior ones tuberculated, and the three anterior with sharp points; they range in a more uniform line than in the bears, which have the anterior cheek-teeth small, and not lasting; the canines of the racoons are flat lengthwise, and straight in their axes; the tails of the animals are also long, but in other respects their bodies are very like miniatures of bears. The carnivorous tooth bears a considerable resemblance to that of the cat family, and thus shows that the habit of the animal is more decidedly carnivorous than that of the bear. The head is large, and triangular in the profile, and the muzzle is slender and pointed, but not so much produced as in the *Coati*; the ears are short, and of an oval shape; the eyes are of mean size, and have the pupils round; the tongue is soft and smooth. The females have six mammae, which are seated in the groin; the legs are short, and they have five toes upon each, armed with sharp and crooked, but not retractile claws. Though this genus of animals is included in the plantigrade group, it is not so decidedly plantigrade as some of the others. It is true that, when it stands still, it applies the whole sole of the foot to the ground; but, when it walks or runs, it raises the heel, and rests on the fore part of the foot only. It is thus a much more nimble animal than the bears; and, though its habits are not very well known, it is understood to be an expert climber, using either the claws or the embrace, as may be best, and speedily getting to the tops of the highest trees. They eat indiscriminately animal and vegetable substances; and in the state of nature they are understood to be great destroyers of eggs. Their sagacity is considerable; but still, as they are not very powerfully armed, they are rather timid animals, and do not approach dwellings with the same hardihood as animals decidedly carnivorous. There are two species, both inhabitants of America, though not of the northern parts of that continent.

THE COMMON RACCOON (*P. Lotor*). This is the one which is best known. It inhabits the warmer parts of America, especially Guyana; but it is rather an animal of concealment, and therefore its manners are but little known. In size, and in the colours of its fur, it bears some resemblance to the foxes, but this resemblance does not extend far; the hairs are white in the middle, and black at the roots and the points, which produces a kind of grey resembling that which covers what are called the black and silver foxes; the tail is deep russet, surrounded by four or five rings of black; the under parts of the body are whitish, and so are the feet and the face, with the exception of a black band, which begins near the eye, and extends down the side of the neck; the claws have more the character of digging than of prehensile claws; the soles of the feet are furnished with five elastic tubercles upon each, one near the heel, one at the base of the thumb of the first toe and of the last toe, and the remaining one between the basis of the two middle ones, which toes are longer than any of the others; notwithstanding that it is partially digitigrade, and does not apply the whole length of the foot at every plant, the racoon is rather a clumsy walker, and their gait may be described as being heavy compared with the true digitigrade animals, though it is light as compared with that of the bears. They can readily stand erect on their hind feet, and lay hold with their fore ones; but this operation of grasping is not performed by the con-

tracting of one paw, but by pressing both together. They do not possess the same pliability in the internal part of the fingers as the quadrupeds, but, by clasping both paws together, they can by this means carry their food to their mouth. The animals have a habit of plunging their food in water, and then rolling it between their paws, before they devour it. Their sight is very delicate, and they have great difficulty in distinguishing objects in the bright sunshine, or any other strong light. In the day-time they generally remain inactive, seated on their posteriors, with the head reclining between the thighs, thus presenting the appearance of a ball; but, in the night, they evince considerable activity in roaming abroad in quest of their food, which consists of worms, insects, fruits, and the roots of plants. They move about in all directions on the surface of the earth, searching the most minute and unfrequented holes and corners in quest of these; and they also climb trees with great dexterity, for the purpose, no doubt, of robbing and plundering the nests of birds. They are particularly fond of drinking water, which they do by sucking it up into the mouth, and there is no necessary of life on which they seem to set greater value, or to relish more. They are said to frequent the banks of rivers and the sea-shore, for the purpose of catching mollusca and fishes, which are their most favourite food. They are very delicate in the sense of smelling, but their organs of hearing are very imperfect. Their appearance resembles the bears more than any other of the carnassiers. Their generally fat condition of body, together with the thickness of fur with which they are clothed, gives them a clumsy rotundity of form. They have an extremely tufted tail, but it does not appear to be employed for any particular purpose in the economy of the animal. They are by no means difficult to tame—soon become familiar—and seem to court caresses; but they do not seem to possess the quality of attachment to their master, or the docility to obey his commands. In order to prevent them from escaping, it is necessary to keep them chained up; for, though captivity softens their nature to a considerable extent, they never seem to yield up that spirit of independence which they possess in the wild state.

Animals of this species have been frequently brought to Europe, and thus people are well acquainted with its form and structure; but very little is known of its economy in a state of nature, as this can never be learned from an animal in a state of confinement. We do not know the period of gestation, or the numbers of the young, though, from the six teats on the female, one might be inclined to suppose that it is considerable. Something must no doubt depend on the fact of all the teats being in the groin, for females which produce numerous litters generally have them distributed over a considerable length of the under part. In some parts of South America there are either different species or variously-coloured varieties, as some are of a rosy hue, and others are yellowish. In other respects, however, they are much alike. The fine fur of all of them felts remarkably well, has a fine lustre, and retains its colour well when dyed, so that it is in considerable request with the manufacturers of hats.

THE CRAB RACCOON (*P. cancrivorus*) is an inhabitant of the warmer parts of South America, where it frequents the shores of the sea and the banks of the rivers, where it subsists in considerable part upon

molluscos and crustaceous animals. The other one is very partial to the same kind of food when in confinement, and therefore has its food and feeding in a state of nature little known. They very probably bear a good deal of resemblance to those of this one. This is rather a larger animal than the common racoon, but it has the tail shorter. The fur upon it is shorter, but closer, finer, and more valuable than that on the other. Its general tint on the back is brownish-ash, produced by the mixture of black, grey, and yellow; the black predominates on the middle of the back, and also on the head and neck, but the general tint becomes lighter toward the sides, where the dull brownish yellow is nearly entire; the feet are brown; and the tail, though short, is marked with a greater number of black rings than that of the common racoon; the end of the nose is black; and a blackish-brown patch surrounds the eyes, reaches back on each side nearly to the ears, and the two portions meet together on the top of the head; the cheeks, sides of the jaws, fore-neck, breast and belly, are yellowish-white. As this species of racoon is less in the woods, and more in the open places, than the former, and as the shores of the wooded parts of South America are the places most easily explored, a little more is known of the habits of this one in wild nature than of those of the other. According to the accounts, its breeding-time is in May, and the litter generally consists of three. The two species have, however, been much mixed up with each other in the popular description; and the racoons and the coatis have sometimes had each other's descriptions applied at rather cross-purposes. Altogether, the animals of South America require to be carefully examined, as the manners of most of them are peculiar, and very little known.

RADIOLA (Dillenius). A small curious annual, a native of Britain, called allseed. The flowers are tetrandrous, and the plant belongs to *Linææ*.

RAFFNIA (Thunberg). A genus of undershrubs from the Cape of Good Hope, belonging to *Leguminosæ*. The species, of which there are several, succeed well with ordinary greenhouse treatment.

RAIA, the rays or skate, or more correctly perhaps, **RAIIDE**, the skate family—a very remarkable family of *Chondropterygous* or cartilaginous fishes, resembling in their physiology the shark family much more than any other; and following in their forms the angel-fish or monk-fish of that family. There are very great differences between them in the details of their appearance and form, as well as in the estimation in which their flesh is held as food; but notwithstanding this, there is a strong family likeness that runs through the whole of them.

They form a family hardly less numerous than that of the sharks. Their bodies are flat and much extended in breadth, with the exception of the tail, which is usually long, slender, and round, and very frequently carries the dorsal fins as well as the caudal one. Though the body of the rays is often much flatter and broader than that of the flounders and other flat fish properly so called, it is not flattened in the same manner. The flat fish is compressed, that is, it is narrow and deep; the ray, on the other hand, is depressed, or broad and shallow. There is accordingly no twist in the head or neck of a ray, and the whole body of it can be symmetrically divided on the mesial plane. The great breadth consists in the extraordinary development of the pectoral

fins, which extend along the sides and run into, and sometimes in advance of, the snout. They do not keep to the banks and the bottoms as the flat fishes do, but range far to sea, and are, like the allied family of the sharks, powerful swimmers. They almost all grow to a great and sometimes to an enormous size; there really not being any known limit to the size, or even the age of any one of them. The broad part is frequently of a sort of rhomboidal form, with two angles in the snout and base of the tail, and other two in the longest parts of the pectorals. The general form resembles that of a paper kite, tail and all. The action of their enormous pectorals is so powerful in the water, that they have been compared in that element to the birds of prey in the air; for as these drive along the sky for long distances, so do the others range over the breadth of the wide seas and oceans.

The backs of the rays are variously coloured, but the under sides of all are white. The eyes and the air-holes are on the upper surface of the head; and the nostrils, mouth, and openings to the gills on the under side. From the position of the eyes, it is by no means likely that they can be of much use to the animals in directing the mouth toward the prey. But the mouth is powerful as a prehensile instrument; and teeth, which are the only bones in the body that acquire the consistence even of true bone, are furnished with very hard enamel; though in many of the species, there are very hard spines upon various parts of the back, the use of which in the economy of the fishes is not very well known.

The gill openings are situated behind the mouth, and they lead to cavities in which the gills remain fixed. The blade-bones of the pectoral fins are articulated upon, or rather soldered to, the spinal column, farther backwards than where the gills are situated; and though the whole motions of the fish are motions of elastic cartilage rather than of articulated bones, they are powerful, rapid, and not nearly so fatiguing to the animals. The tail, which generally has some twisting motions, and is pretty much produced, is by no means an inefficient swimming instrument; although the great pectorals, from their flexibility, are no doubt efficient in producing forward motion, as well as in ascending and descending. Though in the ordinary arrangements of the class, the rays stand near the end, as differing widely from the bony fishes, of which Cuvier very properly takes the perch family as the leading one, and the common perch as the typical species; yet in some parts of their physiology they stand higher than even those typical fishes, and may be considered as approaching in their characters to some of the batrachian reptiles, more especially in their eggs, which are discharged from the body of the female in an impregnated state; and in their skins, which are smooth and without proper scales like those of fishes, but have a tendency to be more or less roughened by spines and tubercles of bony matter. Their skins are lubricated with a copious mucous secretion. It is probable that their sense of hearing and sight are pretty good; but it is certain that the sense of smelling is the most acute one, and the one upon which they chiefly depend for finding their prey. The union of the sexes is real, though not performed in the manner of land animals. This fact has been well ascertained ever since the days of Aristotle; and it has also been pretty well ascertained that the discharge of these eggs is gradual,

and that the fishes are not thereby exhausted in the same manner as those which part with the whole of a large roe at one time. It follows almost necessarily from this that the time of production is carried on through great part of the year, and that the fishes are generally in good condition; though from their ranging habits they are not found in the same fishing stations at all seasons. It does not appear, however, that any permanent attachment exists between the sexes; and indeed attachments of this kind seem to be quite unknown in the whole class of fishes.

The proper cranium of the skate occupies but a small portion of the volume of the head, and, small as the skull is, the brain does not fill it. The vertebrae of the neck, the back, and the tail, the last of which are very numerous, are soldered together; the ribs and sternum are entirely wanting; the rays of the pectoral fins are very numerous, placed laterally with each other, and nearly at right angles to the spinal column; they are jointed at intervals throughout the whole of their length; they taper toward their extremities, and the muscles with which they are loaded, and which have firm fibres in the same direction as the rays, gradually diminish in volume of matter as the extremity of the fin is approached. In many of the species, those muscular fibres, and also some of the softer cartilaginous parts, are very wholesome food; but, generally speaking, they are improved by being kept for several days; and it is a popular remark in some parts of the country, that "a large skate should be used a week as a mat at the door before it is prepared for the table." This species of fish, however, is so very common, that it is held in comparatively little estimation where fish are abundant; but it is on this account highly valuable as food to the poor.

As is the case in the birds of prey, the female rays are larger than the males. The eggs, of which the empty envelopes, which are strong and tough, are of an oblong form, are rounded at the sides and ends, and gathered into a sort of lump or knob. The substance of them bears a considerable resemblance to that of whalebone. They vary from an inch in length to nearly six inches; and in some places they are popularly known by the name of skate-purses. They are sometimes met with in a very recent state, and when they are so, the appendages to the corners are generally longer than in those which are old and dry; and it is understood that, by means of these appendages, the eggs cling to the stalks of marine plants, and are thereby prevented from being washed ashore by the storms. Those which are found adhering to sea-weed are considerably softer in texture than those which are washed ashore; and in very recent ones the white and yolk of an egg may be distinctly seen. There are still some points connected with the economy and hatching of those eggs which would require a little clearing up. Thus, for instance, though it is probable that the eggs grow in size after they are deposited, because those of apparently the same species differ so very much in bulk, yet the fact has not been ascertained in a manner perfectly satisfactory.

Cuvier divides the family into various sections. First, *Rhinobatus*, or shark-rays, which have the tail thick, fleshy, and furnished with two distinct dorsals, and a caudal fin well developed. Their bodies are in the form of a rhomboid, much pointed at the snout, and not so broad in the pectorals as the rays properly

so called. Their teeth are also closely placed in fives, arranged quincunx; but in other respects they are like the rest. The name *Rhinobatus* does not mean shark-skate, but nosed-skate, meaning thereby that the snout is very much produced in them. Some naturalists have subdivided, thereby separating from the rest, certain species which have the same characters of the tail, but the muzzle short and rounded, approaching in form to that of the *Torpedo*.

Secondly, *Torpedo*, which have the tail still stout and fleshy, but shorter than in the long-nosed ones. In them the disc is rounded, and the muzzle divided into two parts, upon each of which a portion of the pectoral fin advances, till their edges are farther forward than the central part of the muzzle. Between the pectorals and the gills in this section there is an electric, or rather a galvanic apparatus, capable of giving pretty powerful shocks in the case of a large fish; but we shall have to notice that when we come to the details of a few of the species.

Thirdly, *Raia*, the rays properly so called, or the true skate. They have the disc rhomboidal, the tail slender, with two very small dorsal fins near the extremity, and sometimes with a mere rudiment of a caudal fin at the end, sometimes with none. Their teeth are slender, and placed in quincunxes upon the jaws.

Fourthly, *Trigon*, sting-rays. They have the disc in general short and obtuse, and each side of the tail furnished with a sharp and hard spine, roughened or toothed, which inflicts very painful wounds, but is not poisoned, as is sometimes alleged.

Fifthly, *Anacanthus*, spineless rays, resembling the sting-rays in the general shape of their bodies, but having the tail long, slender, and without either spines, appendage, or dorsal fin.

Sixthly, *Myliobatus*, sea-eagles, which have the head partly detached from, and in advance of, the pectoral fins; the anterior rays of their fins very long, and the others gradually shortening backwards, till the whole fin has a slight resemblance to the wing of a bird.

Seventhly, *Cephaloptera*, winged heads, which have the pectorals very long, the head in general truncated, and two portions of the pectorals advancing by the sides of the head, something in the form of horns.

In some of these sections the species are numerous, and in others they are comparatively few; but in one or other of their species they are found in almost all seas, some numerous and others rare. The ones which are best as human food are always the most numerous; and this is especially the case in the British seas, where the valuable ones can be had in great abundance; while those that are of comparatively small value, except as curiosities, occur only as stragglers, for the use of naturalists. We shall confine our short notices of the details chiefly to the British species, as they will afford the means of glancing at all, or nearly all, the sections.

RHINOBATUS.—There are several species of this section, all of them having a good deal of resemblance to the sharks; but it does not appear that any of them have hitherto occurred in the British seas, though they are found in the Mediterranean, the Red sea, the seas within the tropics, and in some of the temperate latitudes of the Pacific. The short-nosed ones are found in the seas of China; and there is said to be one on the coasts of Brazil which gives shocks like the torpedo. The species of the Medi-

terranean was the earliest known, and it may be considered as the typical species of the section.

TORPEDO.—One species of the torpedo, or “cramp fish,” has been known as a rare straggler on the south coast of Britain for a considerable length of time. But still, as no very correct description has been given of any of the specimens, the particular species or variety which is thus found on the British shores has not been clearly ascertained.

The Mediterranean is the European sea in which the torpedoes are most numerous. It is indeed, in some respects, a sea of tropical character, far more tropical than the mere consideration of latitude would lead us to suppose. How much this may depend on the volcanoes near its shores, and the volcanic fires under its bed, it is not easy to say, but these have unquestionably a very considerable effect upon it. They appear to have had even more effect in more early times, when they were numerous and more distributed, when the extinct volcanoes in France, which are now separated from the sea by the plain of Languedoc, were near the shore, or rather, when the shore was near them, and they were blazing away in all their majesty. The fossil fishes and shells of decidedly tropical character, which are found in vast numbers in some parts of Italy, especially near the Apennines, furnish the most conclusive evidence of this; and there is a conformity in the characters of many of those that remain at the present day.

In the matter of many of its fishes, the Mediterranean has been fortunate in an observer and describer of the very first order. Risso, of Nice, who published the Ichthyology of that city, that is, of the sea in its neighbourhood, in 1810, corrected many blunders, and added much to our knowledge of the fishes of the Mediterranean, and of none more than of the torpedos.

According to Risso, there are various species of torpedo in the Mediterranean, all resembling each other very closely in their more essential characters, but differing much in size, in colour, in the strength of the shocks which they are capable of giving, and in their numbers and disposition to range. The one most frequently met with is the common torpedo, the *Raja torpedo* of earlier writers, and the *Torpedo narke* of Risso. It is easily known by the number and distribution of the ocellated spots on the dorsal surface of the disc. The ground colour of the upper part is clouded or marbled with white, with russet, and with brown; and marked by five large spots of a blue colour, with brown margins, which render them very conspicuous. Another species not so common is the one-spotted torpedo (*T. unimaculata*), which has the back of a yellow colour, dotted over with small points of white, and one large blue spot on the centre of the dorsal face of the disc. A third is the marbled torpedo (*T. marmorata*), which is without distinct spots on the back, except brown ones; and the ground of the whole upper part is marbled flesh colour. To a fourth, Risso gave the name of Galvani's torpedo (*T. Galvani*), in compliment to the discoverer of humid or chemical galvanic action. It is without any spot whatever on the back, which is of a plain reddish or greyish brown, becoming darker toward the sides. This is the largest of the Mediterranean species, and the one which gives by far the most powerful shocks, though both analogy and observation lead us to conclude that, with equal health, the shock is always violent in proportion to the size of the fish that gives

it. This species is described as being of a more ranging disposition than the others; and in consequence of this last habit, it is probably the one which is occasionally found in the British seas, though, as we have already hinted, the fact has not been clearly established.

Of the figures given by the earlier writers on British fishes, it is impossible to speak with certainty with the view to the ascertaining of the species. The reason of this arises in part from the fact that only one species had been described by the systematic ichthyologists, namely, the common one with the five blue spots margined with brown upon the back. This was always what they had reference to in their descriptions, and sometimes the figures which they gave agreed with this description, sometimes not. Whether they did or did not agree does not appear, however, to be a matter of much consequence, as none of them appears to have been directly taken from a specimen obtained on the British shores. The figure given by Donovan has the five spots, but the source whence he obtained the copy is not known. Pennant's figure, on the other hand, is without them, and the origin of it is understood to have been a specimen, without any spots, obtained on the western shores of France, and most probably the *Torpedo Galvani* of Risso, which agrees with the discursive character which he ascribes to that species; and some other observations tend to confirm this by the large size of some specimens which have occurred. The late Colonel Montague was always attentive to every thing which could advance the knowledge of animated nature, and he mentions a specimen, taken on a turbot hook off Tenby in Wales, which weighed one hundred pounds; and he adds that “it was dead when disengaged from the hook, or the fisherman would certainly have had a shock that would have made him remember the species again.” So unusual was it, however, that the Tenby fishermen knew nothing of its characters, or even of its name, and merely mentioned it as a strange monster of the deep, exhibiting it as such for the gratification of the curious.

The most extraordinary part of the organisation and character of the torpedo is its electric or galvanic apparatus. This apparatus lies in the anterior part, in two lobes or portions, situated on each side of the eyes, and temporal vents which are behind the eyes, but not reaching so far backwards as the gills, or principal articulations of the dorsal fins, thus leaving both the breathing and the swimming of the fish comparatively free. It must be, however, that this apparatus must to a certain extent encumber the fish, and diminish its swimming power; and all who have had opportunities of observing it agree in representing the torpedo as a dull and sluggish fish in the water. It is said to keep on the banks of soft mud, such as are frequented by turbot and soles, and to move about rather heavily, though that does not agree exactly with the ranging character ascribed to the most powerful species. It agrees, however, with the analogy of all other fishes which are furnished with an electric apparatus, and capable of giving shocks; for the *Gymnotus* and the *Silurus electricus* are both dull and sluggish fishes.

In the whole of them the electric or galvanic apparatus is constructed in a manner somewhat similar. It consists of a series of prismatic tubes, arranged close together, with thin membranous walls, and divided into short lengths by cross partitions, a fluid being

contained between every two of the latter. In the torpedo these extend all the way from the integuments of the upper surface to those of the under, their ends being fastened to those surfaces, and their axes perpendicular to the plane of the fish.

It is unnecessary, however, to go into any minute description of these with a view of ascertaining in what manner the energies are connected with the structure. No doubt they are connected with that structure; and the different tubes or columns, with their partitions, and their intermediate fluid, have some slight resemblance to the common galvanic trough. But here the parallel stops, and a new element comes in, which forbids all further comparison. The action of these organs depends upon the life of the animal, being vigorous or feeble, according as that is more or less; and while the electrical fishes benumb the senses of whatever living creature they strike, they become greatly exhausted by the effort, and soon lose their power, until they have rested and recovered themselves; and when life is extinct, the power of giving shocks is at an end, and cannot be revived in the dead body.

This species of electric, galvanic, or whatever other action it may be called, is therefore a phenomenon of life, modified by organisation, and not belonging to, or producible in, dead matter. It tends, however, to show that there is a close connection between the electricity or galvanism of matter and this power of these fishes, though in the fishes it belongs to the life acting by means of organs, and in the other cases it belongs to matter, as such, without any reference to life or organisation. In this it follows the general law of the animal economy: it is a universal property of living creatures to assimilate substantive matter, and turn it into the substance of their own bodies; and the very same law demands that in every case, according as it may be necessary to the part which the animal has to perform in the grand system of nature, it should have the power of assimilating action, and modifying that by its organisation, so as to accomplish those purposes for which it is appointed. But when those modifications, either of substantive matter or of action by a living creature, are introduced, they completely destroy the analogy between the action of animals and the action of inanimate matter; so that, if we attempt to reason from a comparison from the whole of the one case to the whole of the other, we are sure to fall into error; and if we say one word beyond this we destroy the simpler and more useful part of the comparison, which is really matter of philosophy.

There is another circumstance connected with these electric fishes which is worthy of attention, as tending to establish the distinction which we have endeavoured to point out. If the expression may be used, the electric action of matter, in what manner soever it is exerted, appears to act on the matter of the body as obeying the life, rather than on the life itself; whereas the animal electricity appears to act directly on the living principle, and only through that upon the material part of the body.

This may seem a nice distinction, and one which is much too subtle for popular description. Such, however, is not the case; because those nice points of physiological distinction have a far more extensive range than the mere natural history even of animals; and it is in the misapprehension of them that the foundations of our most serious errors are laid. Ob-

servation shows that the muscles, as organs of motion in obedience to the animal life, but not that life itself, or capable of acting without, are affected by ordinary electricity and galvanism; and in proof that they are so affected simply as matter, and not as living matter or life, is established by the fact, that they can excite the muscles after life is extinct, and until decomposition has made certain advances. The shock given by the electric animal does also affect the muscles; but this is not its ultimate or its most powerful effect. Its tendency is to stupify the senses, and take down not the tone of the mere muscular system, but the energy of the life which puts that system in motion.

We have felt it necessary to make these remarks at some length, in consequence of a remark by Mr. Couch contained in a quotation which we shall presently make from Mr. Yarrell's excellent "History of British Fishes," to which we have so often to refer, and always with pleasure. Mr. Couch deserves the greatest praise for the zeal, assiduity, discrimination, and success of his observations. But Mr. Couch must look to his philosophy even with keener eyes than if he were an inferior man; because in him the sterling metal so preponderates, that it is almost sure to carry whatever of alloy may accompany it into general circulation. The passage is as follows, the quotation within single commas:—"The whole use of the electrical apparatus and power to the fish can only be conjectured. That it serves as a means of defence is very probable. Mr. Couch thinks other powers may be derived from it, and his opinion is thus expressed:—"One well-known effect of the electric shock is to deprive animals killed by it of their organic irritability, and consequently to render them more readily disposed to pass into a state of decomposition, in which condition the digestive powers more speedily and effectually act upon them. If any creature more than others might seem to require such a preparation of food, it is the cramp-ray, the whole canal of whose intestine is not more than half as long as the stomach."

"So long ago as the time of Dioscorides, the physician of Antony and Cleopatra, the shock of this fish was recommended for medical purposes, and especially for pains in the head; and this may be considered as the earliest record of the application of electricity to medicine. In later times it was applied to the cure of gout, the patient being directed to keep his foot on the fish until the numbness extended to the knee. Baron Humboldt (speaking of the *Gymnotus*, we presume) remarks, that the will of the fish directs the effect to whatever part it feels most strongly irritated, but only under the influence of the brain and heart. When a fish was cut through the middle, the fore part of the body alone gave shocks."

Mr. Yarrell makes no remark on any portion of this passage which we have quoted; though it appears that his own conjecture of the electricity being a means of defence is far more probable than the conjecture of Mr. Couch. The tail of the torpedo is without spines, or any of those weapons with which the tails of the true rays are furnished, and which weapons they use with no inconsiderable effect, lashing about with the tail, somewhat as a man would defend himself with a threshing flail, or with the *morgenstein* of the ancient Saxons. The tail of the torpedo is quite unfit for this, both from its stiffness and its want of armature; and thus, were it not for its power of giving shocks, it would be one of the

K K

most defenceless inhabitants of the deep, and, as its motions are slow, it would become an easy prey to fishes of more activity and better armed. It may be, too, that this power is exerted in benumbing the prey of the fish, in order that it may be more easily captured, though this is a little more doubtful than the hypothesis of a defence. At all events, those electric fishes do not always direct their discharges against what may be considered as their natural prey. *Gymnoti* certainly do not eat horses as their natural food in the pools and slow-creeping streams where they have their sluggish dwellings; yet Humboldt mentions, and describes in his usual graphic manner, a battle between horses and *Gymnoti* in a large pond in South America. On that occasion the horses were unquestionably the aggressors, though involuntary ones, and they were put to the rout, though the *Gymnoti* were much exhausted by the effort. We think that Mr. Couch's notion of the electric action being a sort of cookery is far more unlikely and untenable than this. Cooking is so exclusively the privilege of the human race, that it has been proposed to distinguish man, considered as a mere animal, by the appellation of the "cooking animal;" and we should be sorry for the sake of those (and they are not few), who have little human distinction, except their love of cookery, to deprive them of their solitary privilege, by allowing "a cold long-winded native of the deep" to share it along with them. We do think, therefore, that Mr. Couch must give up the idea of the cooking; and we have a more weighty reason for this than the depriving of our gastronomes of a portion of their privilege, in order to bestow it upon a fish, of which they cannot even have the luxury of making a delicious meal in return. The flesh of the torpedo is, we believe, eatable, but it is no *bonne bouche*. The objection which we have to Mr. Couch's hypothesis is the avowed confounding of the electricity of the living animal with the electricity of dead matter; and it is this which involves a grand physiological error, which goes much farther, and works more seriously, not only upon the physiology of animal life, but upon the intellectual physiology of man, than those who have not followed out the train of connexion would readily suppose. That he does identify them is proved by his appending, as a note, that "the bodies of animals killed by lightning do not become stiff;" and we have already endeavoured to show, that though the original action may be exactly the same in these, and in all other cases, the modification is very different. We are ready to admit that, considered abstractedly in itself, all action of matter may be the same: but it is fully as certain that every instance of action which can come before us in its results, and it is only in these that it can come before us, takes its particular character from the particular kind of matter, or organisation of matter, in which, as an instrument of action, the result becomes apparent to our senses.

The true doctrine, therefore, appears to be, that the principle is one, and the modifications of that principle many. This is very obviously the case in substantive matter, where all the differences that we meet with seem to be modifications. Experiment shows that they actually are so in all cases to which we can extend our analysis; and that we have not demonstration in every case is obviously owing to the imperfection of our analysis, rather than to any thing analysible in nature itself. There is no probability

that we shall ever, by any refinement in chemistry, arrive at the ultimate atom of matter, that is, at matter which we can pronounce to be absolutely simple. Nor need we expect this, for it is the same with every thing which can become the subject of thought: we can see a portion of the middle, as much of it as is necessary for all practical purposes; but we can see neither the beginning nor the end. This is true in the simplest of all subjects—time, space, and number; and if we find ourselves unequal to the full understanding of these, we cannot hope to understand better the more nice and complicated subjects of the modifications of matter, and of action as displayed in matter.

But, though our knowledge is limited, it is our own fault if it is not free from error so far as it goes; and though we cannot understand the whole of any one subject, that is surely no good reason why we should confound one subject with another.

Yet this confounding is very often practised; and it is more practised by naturalists, especially those microscopic naturalists who investigate the precise minutiae of the production of nature, than by any other class of persons whatever. This is so generally the case, that every minute observer and precise describer of details is almost a synonym for a bad philosopher; and the man who shows us most clearly the individual beauties of nature is the very man who destroys the beauty of the system, and severs the connexion between Nature and Nature's Author. The remark of Mr. Couch on the electricity or galvanism of the torpedo belongs to the class of errors of which we have been treating; and this is the reason why we have endeavoured to explain the true philosophy of the subject. We shall now pass to some examples of another section of the ray family—the rays, or skate, properly so called—which are the most useful to man, and for that reason the most interesting of the whole.

These are numerous in species, and most of the species are abundant in one part of the sea or another. They all have the rhomboidal form of the body, and the muzzle more or less pointed, advancing far in front of the eyes on the dorsal aspect, and of the mouth and nostrils on the ventral. There is not the slightest external distinction of head, neck, and body, the whole appearing a flat rhomboidal disc, with a long and slender tail at one of the angles. The tail, from the peculiarity of its form, and the smallness of the fins upon it, or their total absence, can be of little or no use in swimming, either in forward motion or in changing the direction. The pectoral fins may, therefore, be considered as the sole organ of motion in the true rays, and in this they differ from every other kind of fishes, as in all the others the grand organ is the caudal fin, or where the body is elongated, and that is small or wanting, the flexures of the body. When a skate is swimming at its ease and undisturbed, its motion is peculiarly smooth and gliding, and puts one more in mind of a kite sailing along with motionless wings, than any other motion which we are accustomed to see. There are no doubt constant flexures in the pectoral fins, but these are done so neatly and easily, that the fish appears to slide along without the slightest effort.

In this the skate form a striking contrast to the flounders, and it is one which is worth attending to, as showing how particular parts of the bodies of animals act, whatever may be their form in the indi-

visual. The swimming fins on the margins of a flounder—we say margins, for they are the upper and under margins, and not the sides—are the dorsal and the anal fins, which are the least efficient for motion of all the fins of any fish. They are not directly connected with the spinal column, but have three even bones simply imbedded in the flesh. Whenever, therefore, a fish is thrown upon these as a means of forward motion, that motion cannot be performed without a caudal fin, or flexures of the body, or both. Hence the twisting and wriggling of all the flounder tribe when they do move, and the limited range to which their very laborious motion extends.

Swimming with the pectorals is a very different matter, especially swimming with pectorals so well developed as they are in the skate. The pectorals answer to the fore legs of animals and the wings of birds; and in fishes the shoulder is always better made out than the support of any other of the body fins. In the skate, which has no caudal fin, and no very useful fin of any kind upon the tail, the blade-bone of the pectoral is peculiarly firm, and the jointed cartilaginous rays in the lobes of the fins admit of very free, rapid, and consequently powerful motion. The length of the rays gives great rapidity of motion to the margin of the fin; and as each ray appears to be capable of a separate motion, especially toward the terminal part, the directions and degrees of action on the water are almost countless, fully justifying the comparison that is usually made between them and the most powerfully-winged of birds.

When a skate is excited, and swims with rapidity, there is still little or no flexure or wriggling of the body, that is to say, of the spinal column, the flexures of the pectoral fins being still sufficient to perform the motion. Indeed, the absence of flexure in the spinal column is one of the means of power in the fins, and far from the least efficient means. In this again they agree with birds, in which powerful flyers always have the spine much stiffer than birds of feeble wing. Against that part of the length where the swimming fins of a skate have the most powerful effect, the vertebræ of the spine are soldered together, and they approach more nearly to the character of the bones of common fishes than any part of the skeleton in those cartilaginous fishes which do not require so powerful a use of the pectorals.

In all the motions of a skate through the water, the above notices of its structure and action will show that the tail is quite free, and fit to be used for any other purpose. We have already mentioned that the chief purpose of it is defence; and in the using of it the spine is much rounded, so that the head and insertion of the tail are much more elevated than the middle part of the body. The tail admits of flexure in every direction, which fits it for being an efficient lashing weapon, but makes it less adapted for a swimming organ than if its action were confined to one place, as it is in all fishes who depend much upon its use in swimming. We have been somewhat particular in describing the motions and organs of motion of these animals, because, on account of the peculiarity of their forms, there is a very general notion among persons not acquainted with the economy of the sea and its inhabitants that they are very unwieldy and helpless creatures in the water; whereas, the fact is quite the reverse, and, even among those

fishes which are regarded as models of perfection as swimming animals, there are none who have more command, or even as much command of themselves, as the skate.

As is the case with all animals of great muscular power and activity, skate are very voracious and indiscriminate in their feeding. Their teeth are not well adapted for biting, in the ordinary sense of the word, and the mouth being a sort of slit, without very produced jaws, they do not catch their food with a rapid snap of the mouth. The teeth are in curved tufts, adapted for breaking and bruising; though the full-grown, or rather mature males, in some of the species, at least, have the same rows of teeth directed backwards, and drawn into sharp but not very lengthened points. They feed upon fishes, and also upon crustacea and mollusca, whether with shells or without; and the power of the muscles of their jaws, as well as of all the other muscles of their bodies, is understood to be very great.

GREY SKATE (*R. batis*) is the skate by way of eminence, and the one of which the flesh is so much esteemed as food. It is very common on some parts of the coasts of Britain, though comparatively rare on others. It is a bold and powerful swimmer, and frequently attains a very great size, sometimes weighing two hundred pounds or more; but these very large ones are not so much esteemed for food as those that are smaller. The colour on the upper part is dull greyish brown, and that on the under part dull grey, marked with dark spots; the snout is pointed, and the lines from the broadest parts of the disc to the snout, which are longer than the two remaining sides of the rhomboid, are nearly straight; the breadth of the disc of the body is one-third more than the length; the hinder part of the disc makes a more obtuse angle than the fore part; but, if the measures are taken to the extremities of the ventral fins, the two angles are nearly equal; the eyes are slightly raised above the general surface of the head; their irides are yellow, and each is defended by one elevated tubercle in front, and another on the inner side; the vent-holes are near the eyes, and defended by valves; the dorsal ridge, or rather mesial line on the back, has no spinous appendages as far as the dorsal fins; but below this there is a single row along the mesial line, reaching as far as the two small fins on the tail, which appear to occupy the place of dorsal fins, and a single one between these fins; these spines are sharp-pointed, of very hard consistency, and have their points directed backwards. The male has also spines on the sides of the tail, with the points directed forwards. The mouth is rather wide, with blunt teeth in the young, and sharp ones with the points inclined backwards in the mature species; they have this difference between the young and the adult in both sexes; whereas in others the change is peculiar to the male. The change begins when the extent of the disc is about fourteen inches. This appears to be the beginning of maturity; but no limit is known to the subsequent growth. The claspers, or "tags," as they are called in some parts of the coast, with which the male of all the species is furnished, one on each side of the root of the tail, are long in the male of the grey skate, on which account it is sometimes called the three-tailed skate.

In this, as well as in all the other species that get the common name of skate by the fishermen, the

females get the name of maid, maiden, or lady. They are larger than the males, and more numerous, or, at all events, there are many more of them caught. It has been supposed that the males are polygamous; and it is highly probable that they are so, but there are no means of establishing or disproving the fact by observation.

Skate are most plentiful upon those parts of the coasts where the fry of fishes which spawn in numbers on the shallows are considerably advanced; and the structure of the teeth shows that the mature ones are fully as well adapted for eating fish as for bruising shells and crusts, though the power of their jaws is quite equal to the latter.

The grey skate appears to be more numerous on the east or leeward coasts of the British islands than on the west or windward coasts. On the north-east of Scotland it is particularly abundant, and the fishers salt and dry great numbers of them, but in that state they are very inferior to the recent fish; in these places they are but little esteemed as food, so that a large one may be had for a few pence; but this is perhaps as much owing to the abundance of fish of better quality as to anything else. White fish, haddock especially, if they can be had recent, are always the better the more simply they are dressed; but as the flesh of skate consists of long fibres, not of flakes, it requires more of the culinary art to render it palatable. It keeps longer, however, than the more delicate fishes, and thus it might be made a very cheap fish for inland consumption.

WHITE SKATE (*R. oxyrhynchus*). This species grows to a still greater size than the former, mention being made of specimens weighing nearly half a ton, but, as it is thicker in proportion, its lineal dimensions are not so great. The male is furnished with spines on the upper surface, near the margins of the pectoral fins, opposite the eyes and vent-holes; and again with three rows near the margin of each produced lobe of the pectorals, or "wing," as it may be called. The ventral fins are small, the claspers are very large, and the tail is furnished with a row of spines along the mesial line, and one on each side. The shape of the body, or disc, is quite different from that of the grey skate. The posterior margins of the pectoral fins, up to the greatest lateral extent, form a semiellipse; the extremities of the fins are rounded, and the anterior line upon each side is convex on the middle part, and concave at the greatest breadth, and near the snout. The mouth is also narrow and pointed; the upper surface is of a plain brown colour, without the greyish tinge which characterises the other; and the under side is white, which gets it the name of the white skate; but it is known by different names in different parts of the country. The eyes are near to each other, and furnished with thin sharp spines at the inner edge of each; the vent-holes are close behind the eyes, and both they and the nostrils are protected by valves as in the others. The teeth are, in the mature specimens, still more produced and pointed inwards than in the grey skate, indicating that this one is still more piscivorous.

They are powerful swimmers, keeping much to the deep water for great part of the year, especially the larger ones, but approaching nearer to the coast in summer and the early part of autumn. In-shore they are not so numerous as the grey skate, but they appear to be fully more so at some distance off; and when the fishermen wish to have them in numbers in

the early part of the season, they set their lines farther to sea than they do for grey skate. Of the skate which are salted and dried in the northern parts of Scotland many belong to this species, and in that state they are better than the grey ones; the smaller specimens of both are found at a moderate distance from the shore all the year round, and they are the best for the table in the recent state, if they have reached maturity. At the places where numbers of skate, of whatever species, are salted and dried, the livers are boiled into oil, which is said to answer as well as cod oil in the dressing of leather.

HOMELYN SKATE (*R. maculata*). This is also called the spotted ray, the narrow ray, the sand ray, and various other names. The spots are on the back, of a darker colour than the ground, and ocellated or margined; but they are subject to variation. The shape is different from that of either the grey or the white; the snout is pointed, but not produced; the front sides of the pectorals are concave opposite the eyes; they end laterally in rounded angles, and are then nearly straight to the hinder part, where they form rounded lobes, deeply indented at their union with the body; the spread of the pectoral fins is about one-fourth greater than the length of the body; the eyes are rather large, fortified by spines in front and rear, and there are some hard tubercles and small spines on the snout, especially that of the male; the spines on the mesial line begin about the middle of the length of the body, and gradually become larger and more curved toward the rear as they approach nearer to the middle length of the tail, after which they become smaller again, but not so small as they are on the back; besides this single row, very old males acquire another row on each side, though smaller than the middle ones; the females have the spines and tubercles on the head less conspicuous, or altogether wanting; the colour of the upper part is nearly that of brown sand when wet, but the name of sand ray is given on account of the rough tubercles, like grains of sand, which appear on the anterior part of the male.

This species is by no means rare on the south and southerly coasts, and it is one of the species which are most frequently and abundantly brought to the London market, where the grey and the white skate are not so common. It does not grow to so large a size as either of these, or, at all events, those that are taken are in general smaller, though they are thick, and firm in the flesh; it is also, frequently at least, captured in a different manner. In the northern fisheries the trawl-net is not used, at least in the capture of skate, the price obtained for them not being equal to the expense; thus, excepting on the shores, none but surface fishes are taken with nets there. Both the trawl-net, and the "great-line," as that which is laid in the deep-sea fishing is called in the north, have these advantages. The net is more certain in its capture; but both the net itself, and the working of it, are more expensive than the line; besides its cheapness the line can be laid in deeper water than the net can be worked, and thus it has the chance of capturing larger fish, and capturing them in good condition when they have got to seaward beyond the reach of the nets. Fishing to the greatest advantage would thus require the use of both on the same coasts, and for the very same kind of fish.

The variations which occur in the markings of the

upper part of this fish have caused some confusion in the description of it. In all cases the principal part of the upper surface is smooth, and the conspicuous spots vary a great deal; at times there are only two, one on each side of the ridge of the back, and near the middle of its length; at other times there are several, and at other times again there are none at all. These variations in the spots do not appear to depend in any way upon age or sex, but the spines on the snout, near the eyes, and on the anterior margins of the pectoral fins, are characteristic of the adult male only, and become more conspicuous with age.

THE THORNBACK SKATE (*R. clavata*) is not unlike the last-mentioned species in its general shape, only the notches at the posterior part of the pectorals are not so deep, and the ventral fins are broader. This species is very common in all the British seas, and more easily obtained than some of the others, though not esteemed equal to them in quality; still, however, the flesh is not bad, and in places where fish are not very abundant, or other provisions are costly, it must be regarded as rather a valuable fish.

It has a much greater tendency to the production of spines and tubercles on the upper surface than any of those that we have previously mentioned; the adult male has also the teeth considerably produced and pointed, but that does not appear to extend to the female; the eyes and vent-holes are proportionally larger than in most of the species, and they are defended by strong and crooked spines; the whole of the upper surface is granulated with hard tubercles, which have their bases polygonal or star-shaped, and among these are arranged the spines from which it gets the name of thornback, and which make it not very pleasant to handle even after it is dead. Those spines or thorns are of peculiar form, their bases are oval discs; from the middle of these the thorns arise, not long, but strong and sharp, and with their points inclined backwards, or backwards and obliquely outwards. Their number increases as the fish gets older, and their principal distribution is on the mesial line of the snout, along the anterior or margins of the pectorals, upon the posterior parts of those near the notches, and a few irregularly disposed on the back. These strong-hooked spines are not very numerous, varying from a dozen to twenty or more on each side of the back, and not always symmetrically disposed on the two sides, so that their number and distribution cannot be admitted as a constant character.

The spines on the ridge of the back begin a very little in the rear of the vent-holes, and they are alternately larger and smaller, but none of them are so large as those on the snout and the pectoral fins; the tail is armed with three rows of spines throughout its whole length, and, though individually these are not large, the tail is a dangerous instrument, and must be very formidable against an enemy. Defence against a pursuer is obviously the use of these spines, for they can do mischief only to that which comes upon the animal in the rear or on the flank, the more mesial ones being directed to the rear, and those on the pectorals obliquely outwards.

All the danger of enemies to which these fishes are exposed must come from the plane on which they swim or above it, for the whole of the under part is white and smooth, and quite destitute of every kind of defence; the mouth is on the under part of the body, no doubt, and its teeth are numerous and its muscles

powerful, but still it is an eating mouth only, and not a fighting one. What the enemies may be against which the thornback especially is thus powerfully armed it is not very easy to say, as a large skate, even without any spines upon it, would be rather an ungainly mouthful for even the largest of those fishes which swallow their food and do not bite it. The sharks and grampuses bite, it is true, and the former can hold the prey with one set of teeth while they use another in sawing off the portion within the mouth; hence it is probable that these are the principal enemies against which the skate tribe have to defend themselves.

Armed for its defence in this formidable manner, the thornback appears to have little to suffer from any large enemy save man; we say "large enemy," for there are many little parasitical foes against which the size, strength, and armature of a large animal are of no avail. The thornback, however, appears not to suffer much from any enemy, and not to feel in its number the captures which are made by man. It is abundant on every part of the coast adapted to the habits of skate, and it is so abundant on the Cornish coast that it is the *ray* there. It has been conjectured that the name is a corrupt pronunciation of the Anglo-Saxon *reah* (rough, the *h* being not only aspirated but guttural); but there is little probability of this, as the old Cornish language continued to be spoken in that duchy after the Anglo-Saxon had ceased to be the language of England. Autumn and winter, or rather a portion of time where these meet, is understood to be the prime season of the thornback, though in the season of production it is more abundantly found on the banks; the probability is, that it is firm in the deep water, and softer in the flesh when on the shallows, where it commits the greater number of the germs of its progeny to the keeping of the waters. Like all the rest of the family it is a very voracious fish, and not very particular in its choice. Flounders, crabs, shelled mollusca, or anything that inhabits below it, and can be come at, do not appear to be rejected.

STARBY RAY (*R. radiata*). If many of the other rays are interesting from their numbers and their value as an article of cheap and not unwholesome food, this one has an interest of a very different character. It is rather a handsome fish, not apparently growing to any great size, and it is very rare. The sea which it more immediately inhabits is not very well known; but, considered as a British fish, it appears to be of the north rather than of the south, though the fishermen have no particular name for it on any shore of our seas.

The form of its disc is nearly that of a square; but with the three terminal angles rounded, and the sides a little convex. The ground colour of the upper part is pale orange brown, but is marked with spiny tubercles, differing, however, from those of the thornback. There are no small tubercles granulating the general surface, as in that; but the spiny tubercles are much more numerous: they are largest along the dorsal line, but small ones alternate with the large ones there; there is one in front of each eye, a few small ones along the inner margin of each eye; two or three large ones behind the vent-holes; and some more not far from the dorsal ridge, and nearly opposite the largest part of the pectorals; the rest of the upper part is irregularly sprinkled with smaller ones; and there is a regular row of small ones run-

ning along each side of the row of large ones on the back; the three rows being continued on the tail, which has also a pectoral row on each side. In these spinous parts, or bosses, these are not very unlike those upon the thornback, only they are not so prominent, but the basal parts, or bucklers, instead of being simple ovals like these, have their margins with radiated points like stars; the under side is of a clear and uniform white colour; the eyes are moderately large, well defended by lids, besides the spines; and the vent-holes and nostrils are also rather large, and have membranous valves; the mouth is small; and though many specimens have not been examined, the probability is that the lateral and interior angles of the teeth are produced and pointed in the mature individuals of both sexes.

We are not aware that any specimens have been met with on the south or even the west coast, or indeed on the east coast of England, except in the extreme north. In the "Fauna Groenlandica" of Othon Fabricius, published in 1790, there is a description of *R. fullonica*, which appears to answer to the specimens that have been met with in the British seas; and from this it would appear that the fish is better known in the Greenland seas than in those of Britain. In consulting the work of Fabricius, much stress must not be laid upon names, as he often erred in their application. But his descriptions are remarkably precise and excellent, and may be implicitly depended on in all cases where they agree with a specimen.

The fact of being found on the north and east coasts of Britain, and not on the south and west, is a corroboration of the starry rays being a fish of the northern seas, because part of the "set" of the current on our north-east shores is from those seas, whereas the set of the current to and along our eastern coasts is from the Atlantic. Even in the north, however, nothing appears to be known of the habits of the fish, so that it either keeps much out at sea, or it is rare in any locality where it occurs. It is said to be more common on the coasts of Denmark and the north-west of Germany than with us; but it is not of value in an economical point of view in any locality.

THE BORDERED RAY (*R. marginata*) is a rare species as well as the immediately preceding one; but it comes from the opposite direction, as any specimens of it that have been found have been on the south and south-west coasts. It occurs more frequently on the French coast; and it is abundant in the Mediterranean, well known to the fishermen there, and much esteemed as food. In the form of its disc it is not unlike the Homelyn ray; and like that it has no spines on the body, but those on the tail are more developed than in the Homelyn. The mouth is moderately large; the teeth numerous and pointed; the nostrils about midway between the corners of the mouth and the edges of the pectorals; the eyes and vent-holes large, with a single spine at each of the former; the snout and anterior edges of the pectorals roughened with small tubercles and a few little spines, but all the rest of the body quite smooth; the tail is about the length of the body, rather stout, and a little flattened; the spines in the three rows upon it formidable and curved backwards, the two fins near its extremity very small, and the terminal one a mere rudiment; the ventral fins are of considerable size, divided into two lobes, and notched or toothed in their margins; the upper part is reddish brown,

with very obscure spots of darker; and the under part white in the middle, but marked all round with a border of dark reddish brown, broader at the external angles of the pectorals, and nearly or altogether obliterated at the snout. The south and southern part of the west coast of England are the places where this rare stranger is most likely to be met with, yet some instances of its occurrence on the east coast are mentioned, though only on the southern part.

THE SMALL-EYED RAY (*R. microcellata*) is another very rare species, found only as a straggler on the southern coasts. The specimens that have occurred have been of considerable size, though not large. They are remarkable for the smallness of the eyes and the beauty of the colours on the dorsal surface of the disc; the ground colour of this surface is clear light grey; a white line passes down the dorsal ridge; and there are arches of the same colour near the sides of the disc; those on the front sides begin by small points a little in advance of the eye, and proceed toward the distal angle of the pectorals in curves, with their concavity toward the margin, and the one next the centre of the disc; there are three of them on each side; although the marginal one is smaller and more obscure than the rest. From the angles of the pectorals at which these terminate, or rather vanish, three others begin on each side, curving inwards like the others, having the outer ones small and obscure, and the central ones terminating near the middle of the posterior lobe of the dorsal. These arches form the disc into a set of regular figures, becoming more concave in the sides, and sharper in the angles, as they approach the central one; that one still occupies the greater part of the disc, and is marked with whitish spots, as well as divided longitudinally by the pale stripe on the dorsal line; the eyes, as has been hinted, are very small, but the vent-holes are large, and show much more conspicuous than the eyes; the upper part of the body is rough with granulations, but there are no spines upon it, except a row of small ones on the lower two-thirds of the back, which are also continued on the tail to the fins; and there is another row of very small ones upon each side of the tail; the tail has also very narrow membranous margins on the sides, and the two fins are small rounded lobes, without even a vestige of a terminal fin; the under surface is pure white, and so full of mucous follicles, that their openings appear as if they had been punctured all over with a pin; the mouth is rather large, and the teeth very much resemble those of the thornback. This species appears to deposit its eggs early in the spring, or at least to begin doing so at that time, whereas the more northerly species, which are found in numbers on the British coasts, do not begin till the season is pretty far advanced.

THE LONG-NOSED SKATE (*R. shagrinca*). The English name of this species is given to it on account of the great length of the snout, which is the most remarkable feature in the shape of its disc. That disc is nearly triangular, only the two anterior sides are a little concave in their outlines, and the posterior or third one consisting of the two lobes of the pectorals, which have no cuticle at their termination backwards, is considerably convex; the snout, besides being long, is very much pointed, and its distance in advance of the opening of the mouth is about one-third the length of the body, exclusive of the tail;

the upper surface of the disc is leaden grey, and the surface is beset with tubercles, whence the name of the shagreen ray; there are two rows of small spines on the snout; and the old males have often a tuft of small spines above each eye; there are a few scattered spines down the dorsal ridge, and some near the anterior edges of the pectorals; the tail has one mesial row of small spines and two lateral ones; it lessens to a point, and the fins upon it, and also the ventral fins, are very small; the under part of the body is dull greyish white, marked with dusky spots, something in the same manner as the grey skate. Indeed, in its general form, this species has more resemblance to the grey skate than to any of the others, notwithstanding the greater length of the nose, the rougher character of the upper surface of the disc, and the greater number of the spines on the tail. In the summer it comes upon the banks within reach of the trawl-net; but in the cold weather it betakes itself to deeper water, in which, however, it is highly probable that it could be taken with the hook; and if so, there is no doubt that it would be found in better condition than it is in summer, when it comes into more shallow water for the purpose of depositing its eggs. No mention is made of the long-nosed skate on the north coasts.

The above enumeration contains all the species of this very curious and interesting section of the ray family which have hitherto been found in the British seas. Those that are different from these, and occur in other parts of the world, are of comparatively little interest to the general reader. We must, however, notice one species at least of each of Cuvier's other sections of the family.

THE STING-RAY (*Trygon pastinaca*). This is a curious species. It has been long known, and not a little celebrated on account of the formidable weapon with which its tail is armed. It is distributed over a very considerable range of latitude, and though as a British fish it is rare or unknown, except on the south coasts of England and Ireland, it is met with on the coasts of Norway, and it is common in the Mediterranean. The severe wounds which the weapon on the tail is capable of inflicting, led to a very general belief that the weapon was envenomed. We need not wonder at this, for the same was long believed of the antlers of deer. Ragged weapons, though they of course infuse no positive venom into wounds made by them, yet have often effects more fatal than venom, unless it be venom of the more deadly reptiles, of which the ancients knew but little. The lacerations which they make may bring on great pain, and even tetanus, which was no doubt the cause of these notions of poison. The disc of the sting-ray approximates to the form of a hexagon, of which the terminations of the ventral fins form the posterior and shortest side, but they extend beyond the posterior lobes of the pectorals; the body is smooth on the upper part, excepting a few tubercles on the dorsal line, and others near the posterior margins of the pectorals. It is thicker in the middle than the disc of any of the other rays, but gets thin toward the sides; the middle of the upper part is bluish brown, passing into dull yellow toward the margins; the under part is white; the irides are golden yellow; and the vent-holes opening obliquely behind and outwards of the eyes are very large; the membranes of the nostrils are also large, but the mouth is small, compared with the size of the fish.

The most peculiar part of its structure is the tail; it is very thick, strong, and muscular at the base, tapering gradually to a very slender point, and without the smallest vestige of a fin on any part of its length. About one-third from the base of the tail, the weapon called the sting is inserted on the dorsal aspect; this spine is nearly one-third the length of the body, exclusive of the tail; on the upper and under sides it is flat, but the two edges are serrated with very awkward-looking crooked teeth, and the point is very sharp. In a specimen measuring about two foot in breadth from angle to angle of the pectorals, this weapon is not less than six inches in length. In illustration of the manner in which the sting-ray uses its formidable weapon, we cannot do better than quote a short passage from Mr. Yarrell's "British Fishes," vol. ii., pp. 443, 444.—"Mr. Couch in his MS. says, 'This species keeps on the sandy ground at no great distance from our land, and in summer wanders into shallow water, where it is often entangled in the fishermen's nets—the only way in which it is usually caught, for it rarely swallows a bait. The manner in which this fish defends itself shows its consciousness of the formidable weapon it carries in its tail.'

It shows no such thing, and we sincerely wish that these accurate and excellent observers would learn a little—a very little—of sound philosophy. Consciousness, even in man, is very like one of those words which are invented in order to have the semblance of knowledge in cases where there can be none of the reality; and when we use it with reference to any other animal, it is jumbling man and animal together.

" 'When seized or terrified, its habit is to twist its long, slender, and flexible tail round the object of attack, and with the serrated spine tear the surface, lacerating it in a manner calculated to produce violent inflammation.' Other authors state that it is capable of striking its weapon with the swiftness of an arrow into its prey, when with its winding tail it secures the capture. These spines, as may be supposed, possess no venomous quality: when lacerated wounds happen to men of bad habit of body, the symptoms are frequently severe. In some countries, serrated fish-spines, admitting of easy application by tying, are used to point arrows and spears, which, when thus mounted, become very formidable weapons." Such is the latest, and, we may confidently add, the best account of the mode in which the sting-ray uses its caudal blade; but we are constrained to add, that these notices show upon the face of them that the parties know very little about the matter—indeed they cannot, for the use of the weapon in wild nature; when the fish has its free range of the sea, is not a subject open to human observation. Analogy—and we have nothing else to guide us in such cases—would lead to the conclusion that this caudal blade is a weapon of defence; but in what manner it is used against the natural enemies of the fish in its own element we have no means of ascertaining. Still, the sting-ray is, from the peculiarity of its structure, a very interesting animal; still it is only to the students of nature, and as an object of curiosity, that it has any value; for, in an economical point of view, it has none. Mr. Yarrell says, "The flesh is said to be rank and disagreeable, and when laid bare by skinning, or by cutting into, is very red—a circumstance which may account for the old name of Fire Flaire."

THE EAGLE RAY (*Myliobatis aquila*). This is a rare species upon the British coasts, though pretty well known on the shores of the Mediterranean. In form it differs much from all the other rays that we have enumerated. The head is considerably disengaged from the pectoral fins, so that the eyes, which in most of the others are actually within the disc, are in this one about midway between the anterior margins of the pectorals and the termination of the muzzle. The muzzle is also short and truncated, the eyes much farther apart from each other, and nearer the sides, and the whole head has much more the air of that of an ordinary fish than in any of the other rays. In these there is some difficulty in drawing a line of distinction in the disc between what is the body of the fish and what are the pectoral fins, from the gradual manner in which the one passes into the other. But in the eagle ray the body of the fish can be easily made out for the whole of its length, and the pectoral fins have the appearance of what they are in reality—appendages. On the upper side the body appears elevated above the pectorals, tapering in a sort of spindle shape toward the caudal extremity, and terminating in a very long tail, which tapers gradually, and is very slender at the point. In the distal, and by far the greater part of its length, it is perfectly plain, without either spine or fin. It resembles the tapering thong of a whip, on which account the fish is often called the “whip”-ray. Toward the base it is different; for there there is a little lobe of fin, and under it a serrated blade like that of the sting-ray in form, but not quite so large in proportion to the size of the fish. The pectoral fins in this species are very tiny, pointed, and narrow in proportion to their length, which gives them much of the character of wings. It is generally supposed that, in the sting-ray, in this, and in all the rays that have a single powerful serrated weapon, or an otherwise simple and tapering tail, the weapon is either renewed periodically, or provision is made for the replacing of it by another in the event of its being broken off; for a smaller one has been observed by the side of the large one attached to the same base. The eagle ray has no pointed teeth in the mouth, though the jaws are abundantly supplied with both teeth and muscles. The outline of the jaws is rounded so that the one is capable of having a rolling or grinding motion upon the other, for which reason the fish is sometimes called the “miller.” The teeth are very hard, and nearly flat in their crowns, forming a sort of mosaic pavement upon the jaws.

This curious species is found in the Mediterranean, and in various parts of the ocean, especially in the Pacific and the southern seas, where several other species having similar characters are said to have occurred. All of these appear to be very seaward and discursive; and the character of the mouth and teeth would lead to the supposition that they feed upon crustacea and shelled mollusca much more than upon fishes, though it has been stated, but without direct proof, that they use the caudal dagger in transfixing their finny prey, after having entangled it in the coils of the long tail. This is, we think, very unlikely, and would require to be established by direct observation, which, so far as we are able to ascertain, has not been done. In the absence of such observation, we would say that it is impossible. The tail, though long and flexible, is not absolutely prehensile, and must be regarded as an

instrument for striking, not for grasping. Even supposing that the tail could grasp, and that it actually coiled itself round the supposed prey of the fish, where is the force by means of which the weapon could be made to inflict a wound under such circumstances? Neither it, nor any other spine or weapon with which we are acquainted upon the body of any fish, has any means of motion in or of itself, independent of the motion of the part upon which it is placed. It has not an apparatus for protruding and withdrawing like the sting of a bee, and, therefore, it can inflict no wound, unless it gets its momentum from the muscular action of the body and tail of the fish, acting as one whole. It follows, as a necessary consequence of this, that, in order to use the caudal weapon with effect, the body of the fish must be free. In proof of this, it will be seen that, both in the sting rays and the eagle rays, the weapon is placed near the base of the tail, where that organ is thick and strong, can have little motion in itself, and thus give but small momentum to any weapon, unless the whole body of the fish moves. All this tends to show that the weapon in the tail of these rays has really nothing to do with the capture or the killing of that on which they feed, any more than the electric or galvanic power of the torpedos has to do with such a purpose. It is purely a defensive weapon; and the fact of its being so tends to prove that these fish do not contend with formidable prey. The law is general throughout all animated nature, that, wherever an animal is furnished with defences, it is an animal more subject to be attacked than disposed to attack. Those defensive weapons never in the least assist in obtaining the food of the animal.

“Bulls aim their horns, and asses lift their heels;” but neither the horns of the bull nor the heels of the ass are of any service to them in the taking of their vegetable food. The same runs through all the defended animals: the insects which have stings never use those stings for the purpose of killing or wounding their prey; and the lancet-fishes and others, which have a powerful defence in spines upon their bodies, are most of them vegetable feeders, or feeders upon animals of such small dimensions that the spines could not possibly be used against them. There is no reason why those rays which have their tails armed with formidable spines should form an exception to this general law. We are, therefore, warranted in saying that they do not form an exception to it; and that the conjectures to the contrary are altogether groundless, and calculated to mislead, in a manner far more serious than the individual case, inasmuch as they are at variance with a principle of natural history, from which there is no deviation in nature itself.

That the eagle ray ever made its appearance on the British shores is a point not fully ascertained, though, as the habits of the fish are understood to be discursive, and it is certainly well organised for vigorous swimming, it is by no means unlikely that it should come into our seas; but it does not appear to be a very shoreward animal in any part of the world. Some fragments have been noticed that were supposed to belong to it, but the supposition rests upon very slender foundation. The fish is so curious, however, that it is well worth looking out for by all who take an interest in the inhabitants and the wonders of the deep.

We shall close this brief sketch of the very

interesting family of the rays by noticing at least one of the remaining, and most singular section of the whole, *Cephaloptera*.

These, from the singular projection of a lobe of the pectoral fins in advance of each side of the head, but attached to it as far as it goes, have been called horned rays. They are found in nearly the same seas as the eagle rays, namely, the Mediterranean and the distant oceans; and mention is made of one as having occurred on the shores of North America. Some years ago a specimen was found washed ashore, we believe, on some part of the south coast of Ireland; and the mutilated remains are, or were, in the possession of the Dublin Royal Society, though not in a condition for enabling any one to make out the species.

In their general form the *Cephaloptera* resemble the eagle rays; but they have the distinction between the body and the pectoral fins still more marked, the body shorter and thicker, the fins longer in proportion to their breadth, and the serrated weapon nearer the base of the tail. The eyes are also nearer the extremity of the head (there is no muzzle), and farther apart from each other laterally. The membrane which advances on each side of the head forms a curved margin to the front, with the concavity outwards, and the points advancing till the curved margin forms an arc greater than a semicircle. The under side of the membrane returns in straight lines to the lower part of the head, giving this singular appendage something the appearance of a sort of scoop, with the opening downwards, and bevelled off at the end till the angles at the opening are considerably in advance of the edge between them. The pectoral fins have a solid appearance for great part of their extent, and then a radiated border, which is much larger at the tips of the fins than anywhere else. The anal fins appear as if they were part of this border, only separated from the rest of it by a small notch, and rounded at their extremities. The body has but a very slight resemblance to that of any other fish. It is thick and round, a little narrower at the origin of the tail than at the head, but narrowing rapidly at both ends, and having something the form of an oblong gourd.

The specimen found on the south coast of Ireland measured three feet nine inches from tip to tip of the dorsal fins; but that is nothing to the size of some (whether of the same species as that one or not we cannot determine) that have been seen in the Mediterranean. These are the *Cephaloptera giorna* of Risso. The body is large, turned, elliptical in the cross section, and smooth on the surface, there being no serious appendage except the serrated weapon near the base of the tail. The colour is indigo blue, but with reflections of blackish blue, brown, and violet, when seen in different lights. The under part is dull white, without any reflections. The eyes are silver grey. There are other species, or at all events coloured varieties, in the Mediterranean; but they are not very clearly made out. Some of them are huge fishes, for a specimen has been mentioned which weighed fully six hundred pounds. They appear to keep out at sea; but nothing is known of their manners or their food. Their teeth are, however, much smaller than those of the sting ray and the eagle ray. They are strangely-formed animals; and with them we must close our notice of the family of the rays, which, to

those who study the structure and action of animals, is one of the most interesting in the animal kingdom.

RAJANIA (Linnæus). A genus of West Indian climbing shrubs, belonging to *Dioscoreæ*. The species are stove plants, and are increased by dividing the root.

RALLUS—RAIL, or rather perhaps **RALLIDÆ**, the rail family. A genus of *Echassiers*, or stilt-birds, belonging to Cuvier's macrodactylic or long-toed family. Bechstein and some others have divided them into two genera, from the different lengths of their bills, considering those that have the bill longer as the true rails, and those which have it shorter as crakes; but, for popular purposes, the distinction is of very little use.

Taking the whole of them together, the generic characters are as follow: the bill longer than the head, straight or slightly curved, compressed at the base, and cylindrical toward the tips, the upper mandible channelled; the nostrils opening longitudinally at the base of the bill, in the grooves, open through and through, but in part closed with membrane; legs very stout, bare of feathers to some distance above the tarsal joints, with three long toes to the front and one to the rear articulated on the tarsus, the front toes free or divided to their bases; the wings of mean length and rounded, the first quill being shorter than the second, and the third and fourth the longest in the wing.

Though the rails are entirely without webs to their feet, yet, with the exception of the coots and gallinules, they are among the most aquatic birds in the whole order. In this respect there are differences among them. Some are constantly by the banks of streams, often running along the submerged plants, and sometimes along the water itself, where they move so rapidly that the water actually appears to support their footsteps; while others do not go directly into the water, or even lurk in the aquatic herbage on the margin, but they run about in the tall herbage of moist corn-fields and meadows, where their notes are often and readily heard, though the birds themselves are but seldom seen. Of this the common corn-crake affords a remarkable instance; for there are many districts where its cry is heard from every humid field during the season; and yet where the oldest of the country people never saw a corn-crake, or have the least notion as to what it is like.

The food of the whole genus is understood to be chiefly animal, consisting of worms, mollusca, and such insects and larvæ as are found in the damp and shaded places which the birds frequent. They may be understood as preserving from the ravages of small animals the vegetation of places which few other birds frequent. In one or another of these species they are found in almost all parts of the world where there are water and herbage to conceal them. They very rarely take the wing, unless it be the migratory ones in seasonally changing their habitations, and in these cases they are rarely seen. They do not flock at any season, and they come and go in so stealthy and silent a manner that they are not seen. Those which inhabit the banks of streams are more frequently seen than those which live in the corn-fields and other expanses of tall herbage, but even with them it is only a sight and away. They may be caused to run along the side of a pool where the banks are clear, but they are never far from a cover of bushes or herbage, in which they very quickly con-

ceal themselves. Indeed if one searches the place in which a bird of this kind has taken refuge, the bird is not to be found, neither is there any clue to the direction that it may have taken. Their running powers are so great that hardly any animal can keep pace with them in the cover, and they turn and double with such rapidity, and disturb the vegetation so very little, that they cannot be tracked. Thus, if one rouses the common water-rail in the bed of a stream, and pursues it up the current, it will run and wade and scramble in that direction, but the moment that it gets to a cover it bores through, gains the opposite side, doubles, and never stops till it is farther down than the point at which it was first seen. During the day too they repose in silence and secrecy, and do not rise if they can avoid it. Very early and very late, when the ground is damp, and the mollusca and worms out, are their feeding times, and some of them continue even the whole night long. This is especially the case with the corncrake; and so close does the female of that species sit, that there have been instances of the sithe of the mower destroying her on her nest, without his being aware of her or her nest being there. All the species nestle in as close concealment as they live. The nest is formed in a thick tuft of rushes, sedges, or other aquatic plants, in the case of those that frequent the banks of streams; and those that keep in the cover of the broad herbage, without approaching close to the waters, nestle in that. In this close cover, little labour is bestowed on the construction of a nest, as the nest is used only during the time of hatching the eggs. No ground or running bird exhausts much of its energy in nest-building, and it would be contrary to the general law of nature's economy that it should, for nature never overdoes any more than she fails. The young are able to run and seek their own food almost the moment that they break the shell, but what attention the mother pays to them after is not well known, in consequence of the hiding dispositions of the birds. The family may keep together, and with the mother, while they are very young, but the family are not found in a society after they are fledged; their instinct for solitude and retirement appears to operate at a far earlier age than it does in even the least social of the gallinidæ, which these birds resemble in some particulars, though they differ greatly from them in others. The eggs, as in most ground birds that breed in rich places or in cover of any kind, are rather numerous, rarely fewer than six in the hatch, and often as many as ten. The eggs are generally of a dull sand-yellow colour, mottled with reddish-brown spots, and not very easily distinguished from the withered grass and moss on which they are placed. We shall now notice a few of the species, first of the rails properly so called, and then of the crakes, though we do not think the particular distinctions of them as subgenera or sections are of very great importance.

The true rails have the bill longer than the head, slender, and sometimes slightly arched; the nostrils in the channel of the upper mandible; the anterior toes quite free, and the hind one articulated a little higher up than the others. The head is small, the neck rather long, the shoulders tapering, and the body narrow and compressed, obviously formed for making its way through close bushes and herbage. In its form it is the very reverse of a swimming body, and yet the birds can, upon emergency, swim a consider-

able way, though they never do so if they can avoid it. They eat, in addition to the animal food that has been mentioned, the pulpy seeds of aquatic plants, but they prefer the animal substances. Their pastures are always rich, as they form the most productive portions of the countries in which the birds are found; and they shift about, so as to avoid equally the effects of heat and of drought. They do it in such a way, however, that very little can be observed of their movements. Their slow march is stately, and with long steps; and in their running they bring the whole axis of the body to a horizontal line. Their flight is more rapid and less fluttering than the roundness of their wings would lead us to suppose; but, as is the case with almost every bird of the order to which they belong, they fly with the legs hanging down, ready to alight whenever they come to a locality that suits their purpose. In general they take their repose upon the ground, but they sometimes perch upon bushes, or low branches of thick trees, though they never fly to a high perch, except to get out of the reach of a ground enemy. The predatory mammalia, which lurk and prowl among the bushes near the waters, are their chief enemies; and, as these are chiefly night-feeders as well as themselves, they are on the watch against them. From birds of prey they have not much to fear; for, though bog eagles and marsh harriers often beat over their pastures, the birds are in the cover, and still, at the times when these are on the wing.

THE WATER RAIL (*R. aquaticus*) is the species best known. It inhabits watery places; but the banks of running streams, rather than the borders of fens and marshes, in most parts of Europe and Asia. In some parts of Britain it is not so, as it is rarely seen, but it is not found in the cold and upland districts. It breeds in the country, and remains nearly stationary all the year round in some places, but it migrates entirely from others during the severe weather.

The length of the full-grown male bird is about ten inches, and the stretch of the wings sixteen. The bill to the gape measures an inch and three quarters. The upper mandible is black, except the edges, and the tip of the lower mandible is the same colour; the remainder of the bill, the inside of the gape and the irides are orange-yellow; but the narrow naked border of the eyes is greenish black. The general plumage on the upper part is black, but each feather tells distinctly in consequence of being margined pretty broadly with olive-brown. The feathers on the front have a portion of the tips of the shafts enlarged, and without any webs. The chin, a spot under each eye, and the naked skin from the gape to the eye, are white. The throat, the neck, and the breast, are bluish-grey; and the belly whitish-orange, passing into pure white on the under coverts of the tail. The wings are dusky with whitish margins, the inner webs of the quills broad, and the outer ones narrow. The tail-feathers, which are twelve in number, are also dusky, but their margins are olive. The sides of the body are mottled, and barred with black, white, and some orange. The legs are dusky, naked to about three-quarters of an inch above the tarsal joints; and they and the toes are covered with shielding plates on the anterior and upper surfaces, and with reticulated scales on the posterior, and under. The female is marked nearly in the same manner as the male, but has the bill

shorter, and the dark colours paler; and both birds have the plumage paler in winter than in summer. The nest is in close concealment near the edge of the water. The eggs are nearly or altogether white; they are rather numerous, but the number varies considerably.

The water-rail is a very cautious bird, as well as a very concealed one; and, though each individual, not having the benefit of sentinels, as flocking birds have, must keep its own watch, yet it is very seldom surprised, and still more seldom taken: what with running, wading, dashing across the brook, boring through bushes, brakes, and herbage, doubling, turning, and otherwise shifting its course, it defies both the dog and the gun. There is no very great temptation, indeed, to kill it as game, for, though it is generally fat, the flavour of its flesh is unpleasant. When it can be seen alive, and displaying its agility and its wiles, it is a very interesting bird.

America is much more of a rail's country than Europe or the greater part of Asia; and therefore we must notice some of the American species. The great difference of the seasons in the United States makes the greater part of them migrant in that part of America.

THE CLAPPER RAIL (*R. crepitans*) is one of the most remarkable of the North American ones, and, like our cornerake, it makes itself to be heard all the night long. It is larger than our water-rail, being fourteen inches in length, and eighteen in the stretch of the wings; the bill is two inches and a quarter long, slightly bent, and of a reddish brown colour; the upper part is black, streaked with dull brown; the chin and streak over the eye are brownish white; the fore neck and breast are reddish brown, the flanks and vent black, with white tips to the feathers; the coverts of the wings are dark chestnut brown, and the tail-feathers and quills dusky, without any margins; the legs are dull brown, and the irides dark red.

This species is very common, during the summer, through all the latitudes of the United States; but it keeps near the sea-coast instead of passing into the interior. It is different in habit from the water-rail of Europe, as it prefers the salt marshes to the small streams which scum the dry ground. It is a very noisy bird, especially during the night and before rain, which are of course the times when those mollusca, crustacea, and other small animals upon which it feeds in the marshes, are in greatest activity and most easily obtained. Wilson compares the cry which it utters to that of a Guinea fowl, which is not the most musical note in the world. They arrive in the northern states about the month of April, and, though its flight is not seen, its note is very speedily heard.

Wilson's account of the casualties to which it is exposed in the breeding time is so graphic, that we shall, in part, quote it:—"About the twentieth of May," says he, "they usually begin building and laying at the same time; the first egg being usually dropped in a slight cavity lined with a little dry grass pressed for the purpose, which, as the eggs increase to their usual complement, is gradually added to till it rises to the height of twelve inches or more, doubtless to secure it from the rising of the tides. Over this the long salt grass is artfully arched, to conceal it from the view above; but this very circumstance enables the experienced egg-hunter to distinguish the spot at the distance of thirty or forty yards, though imperceptible to a common eye. The eggs are of a pale

clay-colour, sprinkled with small spots of dark red, and measure somewhat more than an inch and a half in length, by an inch in breadth, being rather obtuse at the small end. These eggs are delicious eating, far surpassing those of the domestic hen. The height of laying is about the first of June, when the people of the neighbourhood go to the marshes an *egging*, as it is called. So abundant are the nests of this species, and so dexterous some persons at finding them, that one hundred dozen of eggs have been collected by one man in a day. At this time the crows, the minx, and the foxes, come in for their share; but, not content with the eggs, these last often seize and devour the parents also. The bones, feathers, wings, &c., of the poor mud hen lie in heaps by the hole of the minx; by which circumstance, however, he himself is often detected and destroyed."

It seems as if the very elements were in conspiracy against these birds: they "are subject to another calamity of a more extensive kind: after the greater part of the eggs are laid, there sometimes happen violent north-east tempests that drive a great sea into the bay, covering the whole marshes; so that at such times the rail may be seen in hundreds floating over the marsh in great distress; many escape to the main land, and vast numbers perish. On an occasion of this kind I have seen, at one view, thousands in a single meadow, walking about exposed and bewildered, while the dead bodies of the females, who perished on or near their nests, were strewed along the shore. The last circumstance shows how strong the tie of maternal affection is in these birds; for, of the great number which I picked up and opened, not one male was to be found among them; all were females; such as had not yet begun to sit, probably escaped. These disasters do not prevent the survivors from recommencing the work of laying and building anew; and instances have occurred in which their eggs have been twice destroyed by the sea, and yet in two weeks the nests and eggs seemed as numerous as ever." This passage would afford much scope for meditating on the physiology of birds; but our limits forbid our entering upon it, and so we must leave it as an exercise for the reader.

If all is well, the young are soon able to run about, which they do with great swiftness, and tread the grass and other marsh plants with wonderful dexterity. They can swim in smooth water, though they are of course ill able to contend with an inbreak of the sea. Swimming is a much more severe action in them, however, than in birds which have the feet webbed or lobed. Though they strike powerfully, their stroke tells but little upon the water; and, consequently, though they strike rapidly, they move slowly. Their feet are for the land, not for the water; and on level ground they run as fast as a man, while among the hummocks, and under the cover of the marshes, they very speedily get out of reach.

THE VIRGINIAN RAIL (*R. Virginianus*) is not, upon the whole, unlike the European species, but it wants the grey on the breast, and has the toes less produced. This bird is not so abundant as the former, and it does not choose its nesting-place so far into the salt marsh, but remains on the margin. It is also found by the streams and pools of fresh water, on which account it is locally called the fresh-water mud hen, while the other and larger one is the hen of the salt water. Its manners appear to be as like those of

the European species as the difference of the countries which they inhabit will admit. Though they are not subject to the same calamities as the clapper rails, yet their eggs are often washed away by the floods. They are much more given to concealment than the clapper rails, and they are not so noisy. In fact, the Virginian rail hardly has a story, after that of the European rail is told, only that it is much more migratory, as most birds are in North America.

The rails of the other parts of the world have got no story to tell, or, rather, they have found no one to tell one for them; but we may name one or two.

THE LAUGHING-BILLED RAIL (*R. ridirhynchus*) is a South American species, measuring nearly a foot in length. The upper parts are brown; the top and sides of the head dull brown; the occiput and upper neck bright brown; the quills and tail-feathers black; the throat mottled with brown and white; the breast and flanks bluish brown; a white stripe from the lower neck to the belly; the rump and thighs black; the fronts of the tarsi red, but the posterior surface of them black; the bill long, blackish, and with the mandibles gaping at the base. There are other rails in South America; indeed the species may be said to be numerous there as well as the individuals, but nothing peculiar is known of their habits. There is, however, one South American species which we may mention on account of its great size.

THE GIGANTIC RAIL (*R. giganteus*). The general colour is blackish, glossed with reflections of green, and whitish streaks along the centres of the feathers; the feathers on the rump, and also the quills and tail-feathers, are without the reflection of green and the streaks. The length is upwards of two feet; but it is doubtful whether this is a true water-rail, and not intermediate between these and the land-rails, or crakes.

In Southern Africa, Australia, the Asiatic Isles especially, and in many of the groups of islands of the Pacific, there are many species of rails. They are indeed one of the most generally distributed sections of birds with which we are acquainted; but, generally speaking, they are birds which come little into view; and, accordingly, the interest of their history bears no proportion to their numbers.

We shall now notice one or two of the crakes, but retaining the same generic name. Their general characters as distinguished from the rails are: the bill shorter than the head, stouter at the base than in the rails, and tapering to a sort of cone; higher than broad at the base; both mandibles of equal length, and compressed at the tips; the tarsi long; anterior toes also long, and slightly margined. The typical bird is

THE CORNCRAKE (*R. crex*). The corncrake inhabits all the humid tracks of Europe and Asia which are covered with tall and close vegetation, but not absolute marshes. It endeavours to find always the same kind of pasture; and, therefore, it migrates equally before the parching heats of the warm latitudes, and the pinching cold of the more polar ones. When it makes its summer appearance in places where quails are also summer visitants, it comes about the same time, and as it has some resemblance to a quail, though much larger, it sometimes gets the name of "king of the quails!"

As a British bird, the corncrake makes its appearance, or rather comes, for it can hardly be said to appear, about the month of April, sooner or later,

according to the place and the season; they go to the inland and upland districts rather than to the warmer places near the sea, and they appear to do this because such places are more moist and subject to rain. They are said to give the preference to slovenly farms, probably because the cornfields in these abound more in the animals on which they feed; they are also said to visit very sparingly those fields which are highly dressed with lime. The birds, as we have already said, are not seen, as they are not only in cover, but, generally speaking, in a state of repose during the day; but in places favourable to them the cry of *crec, crec*, is incessant after twilight and during the night, especially in those northerly places where the twilight is tolerably bright all the summer nights through. They run among corn or tall grass with wonderful rapidity, without making any rustle or sound; and they shift about in such a manner, that, if one crosses their cover, they call upon all sides in turn, even though there is probably not more than one male bird. The call is continued during the incubation, and the object of the male seems to be to keep danger away from the female and the nest, by drawing it upon himself: of course we do not mean that this is a purpose which he contrives and puts in execution as expecting a certain result, because that would require the use of reason, which he does not possess; all that is meant to be implied is that this is the purpose which the instinct serves, though of course the bird himself knows nothing about it.

The nest is very rude, and it does not require to be otherwise, as it is a mere hatching spot, and not a nursery for the young birds. The eggs are very numerous, sometimes as many as fifteen or sixteen, and yet there are very few birds of which the young are so seldom got sight of. The birds linger till about September, at which time some at least of the fields, in which they had been bred in the earlier part of the season, are cleared; but the birds are not very much more seen then than when the fields are covered with tall green vegetation. For a short time before their departure, too, they are silent, and few think of looking for them. They lurk during the day, and, as their colours are not very unlike those of clods and stubble, one may pass close by them without noticing them, the more especially as they lurk singly, and not in families, or even in pairs. If a dog finds one he cannot raise it on the wing without pushing it to the very utmost extremity, and if he gives chase with eagerness it is not destitute of stratagems whereby to throw him out; when the dog is almost close upon it, down it drops flat on the ground, and lies motionless as a stone till he overshoots it in his eagerness, and then it is instantly on foot again, and off in the opposite direction, generally out of the reach of the dog before he can turn.

The *crec, crec*, of this bird, which, in lonely upland places, makes the summer nights rather lively, is not the love song of the corncrake; it is rather the household song, serving, as we have said, to attract the attention of any enemy that might otherwise invade the nest. In the early part of the season, and before the birds are paired, which is of course the time for the love song, the summer cry may be repeated often enough by the closest imitation of the calls of birds, without attracting a single corncrake; but there is another short calling note often repeated, like the sound produced by running a bit of stick very rapidly across the uprights of a close railing, which takes the

ears of the birds in early spring, and is sometimes used in order to capture them.

The corncrake is between nine and ten inches long, and sixteen in the stretch of the wings, and when in the best condition it weighs nearly half a pound. The upper colour is grey, mottled with blackish; the under part reddish white, and nearly pure white on the chin; and the wings are rust-coloured. All the colours are, however, clouded and broken. The bill and feet are brownish ash-colour.

THE SPOTTED CRAKE (*R. perzana*) is a summer visitant in Britain as well as the former, but it is rare and local, being found only in the south and west of England. It is more aquatic in its habits than the corncrake, and frequents the tall herbage by the banks of streams in lonely places; it is a bird better adapted for getting through very close covers, as it is much more slender and not above two-thirds the weight of the corncrake, though nearly of the same lineal dimensions. It gets very fat before its departure, and is then in estimation for the table.

BAILLON'S CRAKE (*R. Bailoni*) is not uncommon in some parts of France, but very rare in Britain; and as it is a bird with short wings it is not well adapted for flight. Its colours are not so mottled as those of the others, and blackish-brown is the upper tint, with the head olive and the nape yellow, and ash-colour the under tint, darker on the belly.

THE LITTLE CRAKE (*R. pusilla*) is also very rare in Britain, and a very hiding bird in its manners. The upper part of it is brown, of different shades in different parts, and the under part is white, passing into cream-colour on the belly.

There are various species of crakes in different parts of the world, the known history of which has but little popular interest. They are not so numerous as the rails, however, and we might be prepared for this by the difference of their haunts. The rails are on the very margin of the water, and wherever there is water there may be a rail's pasture; but the crake is at some distance from the water, and there its pasture may be burnt up and fail, while that of the rail remains.

RANATRA (Fabricius). A curious genus of hemipterous insects belonging to the section *Heteroptera Hydrocorisa*, and family *Nepidae*, which see for its characters. The type is the English linear water scorpion, *Nepa linearis*, Linnæus, which is about an inch and a half long. There are five or six other exotic species. They are all aquatic, but their motions are very slow, their legs being unprovided with the five rows of hairs which are so serviceable to the motions of other allied aquatic insects; the female deposits her eggs in the water, inserting them in the stems of aquatic plants; these eggs are of curious form, and are represented in our second volume, page 834, fig. 15. The larvæ and pupæ resemble the parent insect in their motions and habits, making use of their raptorial fore legs to secure their prey and convey it to the mouth. The perfect insect flies well, but chiefly in the evening and during the night, and is thereby enabled to quit a spot when the water is on the point of being dried up.

RANDIA (Linnæus). A genus of evergreen shrubs, natives chiefly of South America. The flowers are pentandrous, and have some resemblance to those of *Gardenia*. The genus belongs to *Rubiaceæ*, are inmates of our stoves, and require to be grown and propagated in moor-earth and loam.

RANINA (Lamarck). A curious genus of crustaceous animals, belonging to the order *Decapoda*, and section *Brachyura*, having the body of an oblong oval form, the tail extended, and the legs (with the exception of the claws) terminated by paddles, and arranged in two series, the four posterior ones being dorsal. The species are very few in number, and frequent the Indian seas.

RANUNCULACEÆ. The first natural order of the sub-class *Thalamifloræ*, having the petals and stamens inserted into the receptacle. This is one of the most numerous orders of the Jussieuan system, it comprising twenty-nine genera, and above six hundred and thirty-two species.

The frogwort, or crowfoot, and its allies, are herbaceous, very seldom shrubby plants, with aqueous juices, round or irregularly angled stems, alternate petiolate leaves, destitute of stipules, but with dilated leaf-stalks more or less amplexicaul. The disc of the leaf is either entire or variously lobed, seldom compound, sometimes abortive when the expanded petiole becomes a phyllodium; the pubescence, when present, is simple. The inflorescence is variable, either solitary, scattered, racemose, or paniculate; the flowers regular or irregular, and united, or by abortion separate. The sepals are free, definite, from three to six, deciduous, often petaloid, and rarely absent. The petals are equal in number to the sepals, and alternate with them, or two or three times as many, often deformed, being transitional towards either sepals or stamens, or nectaries. The stamens are indefinite, free, and deciduous. The anthers are adnate and two-celled, opening behind by longitudinal chinks. The pistils are numerous, exerted from a ring or torus in one or more series. The styles are free and terminal, short, and often persistent, and the stigma simple. The fruit in general consists of small nuts, or akenia, occasionally becoming baccate, with one or more seeds, or capsular with one or two valves.

The *Ranunculacææ* are in general poisonous plants, as remarkable for the acridity of their juices and venomous properties as for the beauty of their flowers. Their deleterious qualities are so volatile, that in most cases simple drying or infusion in water, or decoction, is sufficient to remove them, and to render the plants innocuous. It is said to be neither acid nor alkaline, but its activity is increased by the addition of acids, or the admixture of sugar, honey, wine, spirits, &c., and that it is only effectually destroyed by the agency of water.

In this order there are many beautiful flowers: beside the ranunculus, there are the peony, anemone, delphinium, hepatica, aconitum, together with the graceful clematis, and atragene climbing shrubs.

The *Ranunculus Asiaticus* is one of our most admired bed-flowers, and its varieties are innumerable: and every year many new ones are obtained from seeds saved from the best breeder flowers. The butter-cup of our meadows is one of the most conspicuous of British plants.

RAPE is the *Brassica rapa* of Linnæus, a common agricultural plant found wild in many parts of Britain. The rape is a biennial, and is chiefly cultivated for its seeds, whence a valuable oil is expressed. It is also sown for winter food for sheep, and it is sown like cress and mustard, for early salad.

RAPHANUS (Linnæus). The *R. sativus* is the

common radish of our gardens, of which there are many varieties. The seed-leaves are an ingredient in salads, and the green pods are used as a pickle.

RAPHIDIIDÆ (Leach).—Snake-fly. A curious family of *Neuropterous* insects, belonging to the section *Filicornes*, having the antennæ setaceous and multi-articulate, the head narrowed behind, the prothorax very long and narrow, forming a slender neck; the wings large, and disposed, when at rest, like the roof of a house; the tarsi are four-jointed. The family, according to Latreille, comprises two genera, *Raphidia*, Linnæus, and *Mantipa*, Illiger. The latter, however, agrees only with the former in the position and neurature of the wings, whilst in the raptorial structure of the fore legs, and more especially in the structure of the mouth, as ascertained by dissections made by the writer, it most certainly belongs to the family *Mantidæ*. *Raphidia*, therefore, constitutes the only genus in the family, and is distinguished especially by its long and slender neck, simple fore-legs, as well as by the long ensiform ovipositor of the female. Mr. Stephens describes six British species, varying very slightly from each other; the type being the *R. ophiopsis* of Linnæus, the body of which is about half an inch long; the wings are large and numerously veined. The insect when alive is extremely active, its long cylindric neck giving it the power of moving its head in all directions, whence the English name of the group. The larvæ are long, narrow, and fleshy, rather broader in the middle of the body; the head large, square, and depressed; the legs, six in number, short, and armed with two terminal hooks. This larva is very active, rolling itself up when disturbed, and twisting itself in various directions; its food, as well as that of the perfect insect, consists of small insects. The pupa is at first quiescent, with the limbs laid along the breast, but subsequently appears to obtain the power of locomotion previous to assuming the perfect state. (See the Memoirs of M. Percheron, in the "Magasin de Zoologie;" and of Mr. G. R. Waterhouse, in the "Transactions of the Entomological Society of London.") The larva resides in crevices in the bark of trees, and it is upon the trunks and amongst the foliage that the perfect insects are found. They chiefly appear in the month of June, and are said to prefer the neighbourhood of streams. According to Mr. Curtis, the ovipositor is exceedingly dissimilar to those of any other insects; it appears to be formed by two canals united, with a space between, being composed of transverse rings, which enable the insect to propel the eggs to the apex, where they are received and deposited by two minute appendages, in clusters like flyblows.

RASPBERRY is the *Rubus idæus* of Linnæus. A wild British shrub, but long cultivated in our gardens for its fruit. The raspberry belongs to *Rosaceæ*, and several new varieties have been originated by the Dutch gardeners, who excel in the culture of this fruit.

RAT (*Mus*, Linnæus, or rather perhaps *MURIDÆ*, the rat family). A genus of rodent mammalia, numerous in species, and beyond all possibility of numbering in some of them. One or another of the species is familiar to every body; and they are among the greatest animal pests in dwellings, storehouses, and magazines of provisions. They are all lively animals, and some of them are very pretty; but there is a "Cain's mark" set upon the whole race, and

"whosoever findeth them" endeavours to "slay" them. Not only this, but there are more engines made for the capture of animals of this genus than for those of any other; and "rat-traps" and "mouse-traps," though not perhaps the very first contrivances of art, certainly had their origin at a very early stage. As a domestic pest, the smaller species, the common domestic mouse, which Linnæus took as the type of the genus, appears to have claimed the earliest attention; as we find it made a character in some of the ancient Grecian fables; and in the *Batrachomyomachia*, or "Battle of the Frogs and Mice," which is usually ascribed to Homer, and which is perhaps the finest burlesque satire on wars and heroes that ever was written, we find them named after the different kinds of stores and provisions upon which they levied their contributions. In the original strife of these mighty combatants, the folly of the mice in being persuaded to go into the pond, for which nature had not fitted them, brings very forcibly to our mind the invasion of Russia by Napoleon, and the fatal consequences of his temerity. There is also something peculiarly fine in the final destruction of the mice by the crabs, which are aquatic animals, and of the frogs by the storks, which are land ones. The fable of the lion and the mouse, in which the monarch of the forest is compelled to beg of this little animal to release him from the net of the hunter, is also full of point. Thus the ancients were, in one respect at least, superior to us in their study of animals. They studied the manners, and by this means contrived to make every animal suggest a moral lesson; we, on the other hand, merely study the forms: and thus, though such of us as are naturalists can as naturalists say much more about them than the ancients could have done, yet they have now far less interest in the eyes of those who are not naturalists than they had then. Thus, though in some respects we have gained, and gained greatly, yet there are others in which we have lost; although *we ourselves* are of course fully convinced that, upon the whole, we have gained.

Taken to the full extent which is included by Cuvier, the rat family is a very numerous one, comprehending not fewer than fourteen or fifteen genera. These have all some resemblances to each other, but most of them differing so much from the true rats in their dispositions and manners, that the same general description cannot be made to apply to them all. Under the title *ARCTOMYS* in this work there will be found some notice of the marmots; under *AVICOLA* some of the field-mice; and various others under their names; so that we shall confine most of what we have to say in the present article to the rats and mice properly so called.

Viewing them thus, the outline of those characters which are common to them will be stated after we notice some of their habits. They belong to a vegetable-eating family, and yet they are all more or less partial to animal substances; and some of them attack living animals, without much regard to size, but when they do so it is still in accordance with the general gnawing character of the rodentia. They do not kill, but begin to eat the living body; and there are instances of rats having in this way inflicted terrible lacerations upon infants and persons otherwise helpless, when neglected by those who ought to take care of them. This has sometimes been pushed to such lengths as to become ludicrous. Mice and rats are known to be very fond of fat bacon, and indeed of

fat of all kinds. Hence we have had stories of them making their holes in the bodies of pigs when kept long in a state of great obesity. We believe that there are well-authenticated instances of the toes and part of the feet of bed-ridden and neglected persons being eaten away by rats; but they, at least used to, carry these matters much farther in Germany; and a curious ancient tale of a Saxon duke is thus transformed from German prose to English rhyme.

"A Saxon duke had grown so fat,
'Tis said that many a mouse and rat
Ate grots and labyrinths to dwell in
His pestick parts, without his feeling."

In addition to this fondness for animal matter, there is little doubt that the mice and rats destroy a vast number of offensive animals and offensive substances. It is well known that the mice are great eaters of those beetles which so much infest houses during the night; and there is no doubt that in cities where there is an under drainage by sewers the brown rats, which make the sewers their principal haunts, contribute not a little both to cleanliness and health. As matters are at present, the drainage of London stains the water of the Thames as much as the fondest admirer of substantial waters could wish for; but when we take into consideration the countless millions of brown rats which are supported in the sewers, and of which the greater part are produced, and live, and feed, and thrive there, without any other store for their support, we can readily understand what would be the case of matters were it not for them. In this view of the matter, the murine races, whether they come under the common name of rats or of mice, are in this respect highly useful, that they play the scavenger for man in cases where he either cannot or will not play it for himself. Every animal indeed which follows man in all his migrations, and multiplies in proportion as his numbers multiply, is always useful to him. Most of these animals are, no doubt, annoying, and many of them are positively offensive; but, in all cases where they are so, man will find that he himself is generally to blame. They come to consume that which is at variance with health and cleanliness; and if the latter is properly attended to, there is no place for them.

In the family under consideration, there appear to be species, chiefly of rats, which are the most powerful and efficient; suited to different states of society. This is well exemplified in the two species of rat which are found about habitations in Britain, and indeed in most temperate countries—the black rat and the brown one. The black rat is the oldest inhabitant of the country, or, at all events, it was plentiful in former times, when the brown rat was comparatively rare; and its numbers have fallen off very much, while those of the other one have increased in a far greater proportion.

The usual method of explaining this is to say that the brown rat has eaten up the black one, and done so to absolute extermination in many instances. But both the analogical presumption and the observed facts are against this. If the brown rat had come to eat up the black one, the increase of its number should have become less, and so indeed should its numbers altogether, as those of the other were eaten up. The fact, however, is exactly the reverse of this; for the brown rat has, in all cases in which observation has been made, increased much faster after the total disappearance of the black rat than it did before.

Besides, there are some parts of the country where both species haunt the very same buildings, and there is no account of any instance in which the one species made an attack on the other. Rats, as we have hinted, are not very particular in their eating; and, if pushed to extremities, it is very likely they would eat their own species; but this is not their general food, for we know of no animals, even in the sea, where cannibalism is by far the most common, far less on the land, which are entirely, or even chiefly, self-supported in the way of food. This would, in fact, be defeating the grand purpose of nature, which runs through and is observable in all that lives and in all that grows, namely, that of each being supported upon the surplus of another.

When they have been found together in the same house or other building, these two species of rats have always taken up separate localities; and localities which show that they are adapted to different states of society, or, which is the same in effect, to become of different character and construction. The black rat is properly a murine animal, lodging in holes of walls and crevices of roofs, and therefore it lodges higher than the other. The brown rat is more an animal of the foundations, loving cold and damp, and preferring a sewer or drain to a palace. As inhabitants of the same building, therefore, the two do not come upon each other's ground in such a way as that the one could exactly replace the other, and this leads us to the particular state of men and their dwellings, in which the one or the other is likely to be the common rat.

Mud walls, and turf and thatch roofs, are the places for the black rat, because it can most readily find or form a lodging for itself there; and although during the night they may range on the ground, their escape is always to the upper part of the building. There is no better authority than Burns as to the conduct of all rural creatures, and indeed all creatures whatever that came under his observation. In his time, whatever may be the case now, those parts of Scotland to which his observations were principally directed abounded much in mud walls, and still more in thatched roofs—in roofs particularly well adapted for affording lodgings for the black rat, in which it could rear its litter, or hide itself during the day. In "the Vision," where he gives so true a picture of the temporal privations to which he was subjected in consequence of his devotedness to the muse, he, without specially intending it, throws more light upon the habitation and character of the black rat than all the professed naturalists have written on the subject. He says that, as he sat "right pensilie" by the fire in the "spence," or inner room of the rude old-fashioned farm-house, "musing backwards on misspent time," he

"Sat an' e'ed the spewing reek,
That filled with host-provoking smeeke
The auld clay biggin';
An' heard the restless rattans squeak
Aboon the riggin'."

Burns did not, like the "starveling bards of these degenerate days," who gather poppy petals for the fine but fading winter nosegays of easy printing, use to hunt for inapplicable epithets to make his rhyme clink. With him, wherever he came by the art, the word which is best in rhyme is always best in reason too; and on this account he is a first-rate authority in all points of natural history which he touches. The "auld clay biggin'" is 'the very place for the

"restless rattan," which always means the black rat; as the word was fashionably cut down to half its number of letters before the brown rat was common in the country. The "riggin'" is also the very place of the roof for the black rat. We need hardly say that "riggin'" is merely the Scottish mode of pronouncing the word rigging. A strong tree or pole, laid from end to end, is the "riggin'-tree," and by way of eminence the "roof-tree" of these old-fashioned houses; and so essential is this to the stability of the houses, that it was the emblematical word for the chief of a clan, or the master of a house; it is even the same in the English language. "Husband," *q. d.*, "House-band," is the very same idea as this; for the "riggin'-tree," or "roof-tree," is "the band of the house." The poor vassals used sometimes to feel this in a very cruel manner; for if a barbarous chief wished to drive a number of them from any locality, he sent his myrmidons to pull all their roof-trees during the snow; and down fell roof, snow, and all, destroying their few sticks of furniture, and driving them and their children, and, in most cases, their sick, homeless and foodless, to the snowy desert. An instance of this occurred as recently as in one of the early years of the present century. It was during a heavy snow, and many roof-trees were drawn. Our present business, however, is with the rats.

This "riggin'" forms a very convenient lodgment for whole colonies of them; for the way in which the rest of the roof is applied leaves a vacant space over it, which is covered by the thatch, and farther made warm and dry by an external ridging of turf, or some other protecting material. This is, therefore, the appropriate place for the black rat; and it is most partial to an apartment in which there is a fire. In such places they often set up a terrible squeaking; but as it is usually in concealment, there is no knowing whether love, war, or family discipline is the principal cause; though each may be a cause in turn. Even in barns and other outhouses they prefer the roof, and are rare in places where that is not suited for being their abode. This also is noticed by Burns. When one of the "lasses" went to the barn to lift the veil of futurity by dire incantation there, a frightened black rat is described as frightening her still more than she had frightened it.

"A rattan rattled up the wa';
An' she cried Lord prescrive her!
An' ran through midden hole an' a',
Prayin' wi' zeal and fervour."

The escape of the rattan, which the entrance of the damsel had probably disturbed when at its supper in the corn-bin, or heap, was "up the wa'," to seek safety in the roof; and indeed in all allusions to this species of rat, running up the wall is mentioned. There is a puzzle in pronunciation common among the children in the country places of Scotland, which confirms what is said by Burns, and completely establishes the habit:—

"The rattan lap up the wa'; loup, rattan, loup."

These matters are of some consequence in the natural history of rats. Rats are associated both literally and figuratively with many points of domestic story; and as, in modern times, the brown rat is the only known rat in most parts of Britain, it is found that the rat of history and the rat of personal observation do not agree; and of course the historical one is put to the wall, and the whole point of it, and story concealed under it, are lost.

The brown rat does not take possession of the roof of the house, and its escape is more frequently downwards than upwards. It is, in fact, much more different from the black one in manners than it is in appearance and colour; and the places where they are met with in the same building are few and peculiar, generally where some "auld clay biggin'" stands in a place where all around has been modernised, where the houses are formed of such materials, and so built, that there is no shelter for a rat in the roof. It does not appear that the black rat was ever much of a city rat, or resorted to houses built of masonry and roofed with tiles or slates, though in the thatched towns, which, being generally enclosed, and often having farm or dairy buildings attached to them, partake more of the character of concentrated groups of country houses than of towns in the proper sense of the word. It also used to be said, and, so far as our observation goes, there is some truth in it, that rats never haunted the poorer cottages, but abandoned them to their more small and feeble congeners, the mice. On this account rats were accounted concomitants of riches, just as the gout is so accounted in other states of society. The truth appears to be pretty much the same in both cases. The gout appears to come chiefly in those cases where the quantity ate and drank is too great for wholesome assimilation, or, at all events, for the proper supply of the waste of the body. This waste bears always a proportion to the quantity of exercise to which the body is subjected when that exercise is not carried to undue severity, and thus indolence aids excessive supply in occasioning gout. Gout may thus be said to be the effect of, to use a homely word, "a litter in the system"—useless lumber lying in the way of the working parts; and if this "litter" is removed, there is no more gout. Now, the case of the rats is exactly parallel to this case of gout. It is not the wealth and leisure of a man that brings this painful and little-pitied malady upon him; it is the improper use of them; and, in like manner, it is not the wealth that may be in the house, but the fact of substances tempting to rats lying littering about, that brings them; and upon this principle a tidy house is always less infested with them than a slovenly one. This may be, in so far, true of the brown rat as well as of the black one, but it is by no means so generally true. Clean houses, and plentifully-supplied sewers and drains, are the places for the brown rat, which, so that it gets enough, is perhaps less particular as to the quality and cleanliness of its food than any other animal that could be named: all carrion, all garbage, all refuse and slops, so that there is animal matter or vegetable matter in them, recent or in a state of decomposition, are welcome to the brown rat. Instances have occurred in which there were none but black rats in the old-fashioned parts of a town where there were thatched roofs, stagnant pools, and no underground drainage; while in those parts of the very same town which were modern, clean, and well drained, there were abundance of brown rats in the underground places, but not a single black one in any part of the houses.

Such appear to be the chief reasons that bring these two species of rats each to or near the habitations of men, when these habitations are in a particular state; and the fact that the black rat has disappeared from most parts of Britain, and the brown one come in its stead, proves that the houses and

habits of the people have become more cleanly, and not by any means that the one species of rat has eaten up the other. In wild nature, the attack of animal upon animal is never carried on to extermination even as between prey and prey. On the contrary, they appear to increase and decrease together. The lions of western Africa prey upon the antelopes and the quaggas, but these animals never fall off much from the usual average of their numbers; and if the state of things with regard to any other preys and prey in any other place is examined, it will lead to the very same conclusion. Any other means would not do. The prey may exist without the preyer, and under that state of things its numbers may increase farther than they do in free nature; but the preyer cannot possibly exist without the prey.

We have preferred making these comparisons of the two species of British house-rats here rather than in the notices of them as species, because here we can refer to both with equal ease and without repetition. The comparison is necessary in order to a right understanding of the animals; and from their numbers, and the frequency of their appearance, to say nothing of their boldness, their briskness, and the services which they perform, rats are among the most interesting of all our wild mammalia. Their history is also both old and familiar; and this is one of the reasons which renders a clear distinction between the two so very desirable, the old history being wholly that of the black rat, and the current history as completely that of the brown one.

It would have been singular, if so bold, sharp-looking, and strong and daring an animal as a rat is, and so familiar as people must have been with it from the earliest time at which their houses could shelter and feed a rat, had escaped without having some marvellous story fastened upon it; and supposing the story to exist, it would have been still more wonderful if some writer *about* animals, full and overflowing as a fountain with the most ready, willing, and universal belief, had not given the public the benefit of the story with a certificate of its truth.

† The story that rats anticipate the fall of a house, and take their departure while yet they can do it with safety, is one of the most current stories in the whole old coin of speech. So generally and so readily has it been believed, that it is made the foundation of the common name of all changes of party and opinion, all tergiversations when taken in the bad sense, and especially in those of a political nature. Tergiversation of this kind, more especially when it consists in deserting one party in its weakness, and going over to the opposite one, in its strength, for the sake of personal advantage, is invariably called "RATTING;" and it is held, and very properly held, to be the worst species of political crime of which a public man can be guilty, and characteristic of the very meanest cast of mind and lowest depth of political corruption. In private life there is probably a great deal more of this rattling than in public life, for it is the way of the world, to use an every-day proverb, that a man can always find plenty of friends when he does not need them, but few or none when he really does. The prevalence of this, even to "a beam," in the eye of the generality of men in private lives, ought to make them a little forbearing in the matter of the "mote" of political rattling; but it does not; and it is possible that men make much of their outcry and noise on political subjects merely for the

purpose of concealing what they themselves do in private society, just as the idolatrous Jews beat drums, and made all other sorts of din, in order to drown the cries of their helpless children which they were burning in sacrifice to Moloch in the valley of Rimmon, in the vain hope that they would thereby procure pardon for their own sins.

Even granting the truth of the story upon which this name of rattling is founded, there is very great injustice done to the rats. Admitting that they quit the house previous to its fall, their so quitting it does not tend, in any way, to accelerate the said fall; for rats, though they may take up their residence in a house, and thus be in some sort members of the household, never, in any way, contribute to the stability of the house, or in the least help one house in the demolition of another. Upon this plain and simple ground, therefore, the epithet "rattling," as applied to an influential member of one party going over to the opposite party, is a misnomer. If the word is to be used at all, it should be applied only to those hangers-on upon a party which live at its expense, and render it no support in return; and the "rattling" of such is, under all circumstances, an advantage.

But the fact that rats do leave a house, in *anticipation* of its fall, is not only untrue, but impossible. There are no means of what we call anticipation possessed by any animal; and the belief that there are, belongs to the very worst species of superstitious delusion, and is one of the very worst parts of it. Animals, being more completely under the influence of natural circumstances than we are, are very often sooner affected by changes; but still the change must happen before it can possibly affect the animal, whether it happens to such a degree as affects us or not. To suppose that an animal, which shows not the least symptom of ever proceeding upon the precepts of cause and effect, can be affected by any change or event whatever, before that event happens, is just about as absurd as to say that an animal could be shot with a leaden bullet, while that bullet remains as galena, in sulphate of lead, in an unopened part of Minera or Halkin mountain. It is even something worse than that; for it is *de facto* making a god of the animal, endowing it with the power of knowing without any means of knowledge. It is astonishing how much language is made the source of the most mischievous of all errors, by the working of these dogmas of superstition into it.

Granting that a rat were the most sensitive of all animals to coming changes, and that it felt them in the very dawn and twilight of their existence, the fall of a house does not come within the class of which its sensibility would give it this early warning. Whatever these are, they must be all purely natural; and though the fall of a house cannot be called an operation of art, it is an operation which could not be produced unless art had been previously employed in building the house, and it is an operation which art, judiciously applied in the repairing of the house, could have prevented. The cause of the fall, therefore, belongs to the category of art, not to that of nature.

It follows, as a necessary consequence of this, that, if rats quit a house in anticipation of its fall, they must understand what are the frail parts of it; and, by understanding this, they must, of necessity, understand how it could be repaired, and the fall pre-

L L

vented. If so, they might be turned to excellent account as surveyors, especially in the matter of such works as the sewers and subways in and about London, which are not very pleasant places for human surveyors to examine. The rats are also always in those places in great numbers; and if they possess the knowledge, there must be some means of getting them to communicate that knowledge. If they know that a house *is to* fall, they must, on the very same principle, know that a sewer *is to* get out of order, because there are no means of knowledge open to them in the one case which are not just as open to them in the other. The notion that rats abandon a house in anticipation of its fall must, therefore, be held as nothing but a piece of superstitious nonsense, and, consequently, all that has been founded upon it, with regard to the conduct of men, must fall to the ground.

It by no means follows, from this, that rats may not desert old houses, and that to the very last rat, in a very short period of time; and it is certain that rats, the black ones especially, migrate in flocks on some occasions, though we are not informed that any unusual falling-off of houses follows these migrations. The probability is, that they migrate in search of food, and quit places which no longer afford them subsistence and shelter. These are no doubt the real reasons why they quit old houses, just as they are the real reasons why they are not found in the cottages of very poor people, which do not afford food for a rat, or in houses of modern construction, in which a rat can find no shelter.

On this subject we shall quote a passage from Mr. Bell's very pretty book on "British Quadrupeds," now in course of publication. We do this for three reasons:—first, the book is very carefully written and very beautifully illustrated; secondly, the passage which we shall quote contains much valuable matter respecting an animal the facilities of observing which are diminishing every day; and thirdly, because there is a quotation contained in it which calls for a remark or two. "Although," says Mr. Bell, "its disposition appears to be naturally exceedingly ferocious, there are instances on record of its evincing considerable attachment, not only to each other, but to mankind." There is a slight depression of the skull of Priscian by the hit here, but *n'importe*. "Mr. Jesse, in his usual amusing and pleasant style, gives us an anecdote, which the respectable authority from which he derived it forbids us to doubt, exhibiting a degree of tenderness and care toward the disabled and aged members of their community, which, were it imitated by Christian men, would either render our poor laws unnecessary, or remove the disgrace and opprobrium which their mal-administration too often causes to attach to them." The reader will please to mark this with particular attention; it is meant to be very pathetic and philanthropic, and we shall have two words to say upon it, after we have heard Mr. Bell and his informant to the end. Now for the anecdote:—"His (Mr. Jesse's) informant, the Rev. Mr. Ferryman, walking out in some meadows one evening, observed a great number of rats migrating from one place to another, which it is known they are in the habit of doing occasionally. He stood perfectly still, and the whole assemblage passed close to him. His astonishment, however, was great when he saw an old blind rat, which held a piece of stick at one end in its mouth, while another

rat held the other end of it, and thus conducted his blind companion. It appears also, from several instances, that this animal is not insensible of kindness, and that it may be powerfully attached to those who feed and caress it." So far Mr. Bell and his respectable authorities. We trust we have shown already that we have no *malice prepense* against this active and ferocious little beast; and so, as we wish to hold the scales even between rats and ratters, we must look to the high character which is here given to the black rat, as a schoolmaster to "Christian men" in the nobler works of Christian charity. If the rat really deserves this high character, then he ought to be exalted above all beasts, whether quadrupeds or not; but if the character is a false one, then all who are concerned in the imposture ought to be made to feel it. But before we can be quite sure of the merits of the case, we must look at "the act."

Now we find that, in the whole code of animal legislation, there is no such thing recognised as any sort of kindness to the "disabled and the aged," but quite the contrary. Dogs always worry the dog that is down; the herd forcibly eject the stricken or the hunted deer; and, among animals of every kind, the weak are always driven to the wall. This is not only what actually is, but, if the expression may be allowed, it is what should be. There is no place in the economy of nature for an old and useless animal, any more than there is for a withered leaf, farther than the gathering of it to the common store of materials. This does not apply to human beings, because there is a part in them which does not partake in the "disabled and aged" state of the body, though its connexion with material nature is of course weakened by bodily decay; and, for the sake of this, the existence of which is demonstrated by Christianity only, "Christian men" are bound to cherish the aged to the very last. With animals it is quite the reverse; their affection, if instinct ought under any circumstances to get such a name, is all for the young and the vigorous; and their attacks are directed against the feeble and the exhausted. If there is any hospitality in them, it is Homer's hospitality—"Welcome the coming, speed the going;" and many of them, and the rats and mice among the rest, even in the most small and delicate of their species, have no objection to Malthusianize, by applying the "positive check," and eating the superabundant population of their own nests. We find therefore that the statute is against Mr. Jesse and his authority. Then for the facts of the particular case.

Mr. Jesse is a great zealot in the observation of all sorts of productions and phenomena in nature; and, moreover, he is a great zealot for the truth of stories, and the more the story is out of the common way the stronger appears to be Mr. Jesse's desire that it should be true. But though we state this as a general inference from the tenor of Mr. Jesse's writings, and think that he has it in common with all zealous observers who are very amiable and not very profound, we must dismiss the present case both as against him and his informant; for the very same story has been told and believed before either of them was born, and long anterior to that. We have heard it in fifty places, and that from people who had no communication with each other. The first time we heard it was forty years ago, from a man turned ninety; so that if time gave validity to stories as well as to the possession of estates, the truth of

it ought to have been fully established many years ago.

It might be as well, however, to "call" the Rev. Mr. Ferryman; as there are one or two questions to which his answers would be very desirable. How many black rats make a "great number," for the breed is getting rather scarce? How near to him did they pass? and at what rate were they moving? What kind of pace had they? did they walk, or trot, or leap, or amble, or gallop? How near must one be to a rat when in motion, in order to ascertain whether the said rat is or is not blind, if its eyes happen to be shut at the time? Satisfactory answers to all these questions are necessary, in order to establish any thing like a hypothesis in the teeth of the general law of nature, as it happens to be here; and much more are they necessary for the establishment of the fact. We believe that rats never migrate till they are starved out at those places which they quit, and nearly at the extreme pinch of hunger, which they can endure a long time, voracious as they are. In their hunger they snap at all sorts of substances, especially if an animal or animal matter has touched them; and although they prefer animal food to vegetable, and vegetable food in proportion as it is pulpy and savoury, yet, as is the case with most of the rodentia, they will gnaw straws and twigs in the extremity of their hunger. We have fifty times seen straw cut to chaff by the teeth of these same black rats; and therein we think may be found a complete explanation of all the tenderness and care towards the disabled and aged, without any infraction of the general law of animals. One rat gets hold of a straw or bit of stick, not with his chisel-shaped incisors, which would soon divide it, but with his tuberculated cheek-teeth; another seizes the end of it in the same manner, in order to pull it from him; and onward they move in their contest.

In all the species, the tendency to production is very great; and, where they have food and shelter, and moderate warmth, it is not confined to any one season. As the rats, that is, the black rat and the brown rat of this country, never live but in situations where they are less exposed to the weather than some of the mice, there is little or no pause in their activity in the whole course of the year, and they breed as readily in winter as in summer. It is in fact their love of a uniform and rather high temperature which brings them in such numbers to the subways and sewers in cities. In these the temperature, taken on the whole, is never nearly so low as that of freezing, and it is generally much higher, often indeed it is absolutely warm, when the free air above is cold. The number of young in a litter is often considerable, exceeding that of the teats of the female, and in some cases double the number of these. The teats are six in number, and the young are often twelve. Many of the other rodentia are very prolific animals, but the rats are to be considered as the most prolific of the whole, especially in situations in which their breeding is not suspended seasonally.

The general characters which distinguish the genus from the other rodentia may be stated thus: the teeth consist of two incisors, no canines, and three cheek teeth in each side of each jaw. All these teeth have roots independently of the coronal part which stands up above the surface of the jaws; the crowns of the cheek teeth are tuberculated, and thus bruising teeth rather than grinding ones; and the incisors are firm,

strong, hard in their enamel, sharp in their edges, and well adapted for gnawing. There are few animals which can gnaw their way through a board more expeditiously than a rat; and even the most diminutive of the mice can eat their way, by runs and galleries in every direction, through a rick of corn, which is very acceptable quarters, and prevents them from feeling any winter when the fields are bare. The ears of the genus are generally large, of an ovate or rounded form, and well developed; and it is understood that the sense of hearing in all is very acute. Their habit requires that it should be so, as they are chiefly nocturnal in their feeding, and not often seen abroad during the day, though the cries of the field ones are often heard from under cover, if the weather is dry and sultry. The ears are usually nearly naked of fur; and none of the genus have cheek-pouches to the sides of the mouth. The feet are plantigrade, and in most instances almost naked, or covered with very short fur thinly set; the fore feet have only four toes fully developed, the one answering to the thumb being merely a rudimental tubercle, though it is furnished with a little flat nail; the nails on the other four toes are well adapted for digging, and the articulations of the shoulders are fortified with clavicles for this purpose, so that the animals can bring the fore feet to the mouth in feeding; the hind feet have all the four toes fully developed; the tail varies in length, but it is generally long, naked, except a few short hairs, and it is covered between them with a sort of scales, which are not true scales however, but merely little hardened plates of the epidermis, which easily fall off and are replaced by others. The principal fur is very soft, but it is generally interspersed with larger and thicker hairs which are shining in their lustre. In place of these last, the spiny rats (*Echimy*s) have their spines, though these are sometimes concealed in the fur. When they live in constant warmth and shelter, they have the produced hairs less abundant than when they are more exposed to the weather. Many of them take the water readily, and preserve their fur dry; but there are some which are easily wetted. They are all, however, very fond of drinking, which operation they perform by lapping with the tongue.

Destructive as the genus *Mus* are in themselves to all those matters on which they feed, and fast as they multiply, where the abounding of their means of subsistence, and especially the continuance of it all the year round, are favourable to their multiplication, they have many enemies to thin their numbers. We have evidence of the avidity with which they are sought by the smaller of the feline tribe, in the domestic cat, which is always on the *qui vive* whenever there is a mouse stirring, and watches and steals upon them with such consummate art that she captures them readily under circumstances where the capture appears to us to be very difficult. The owls (see the article OWL in this work) are even more destructive of them, especially the field and forest ones. The kite also makes many a meal of mice, and in this way makes some slight compensation to the farmer for the few chickens which it contrives to steal from the outskirts of the brood, when the brood-hen is off her guard. The weasel tribe are, however, among the fittest of their foes, as the little and slender bodies of these animals enable them to twine into places where no other of the same power can enter. In wild nature indeed, the weasel tribe, in one or other of

their species, are always numerous in proportion to the food and consequently the numbers of the murine rodentia. About a farm-yard, one weasel or ferret can do the work of a dozen cats in the destruction of mice; and in as far as vegetables are concerned, whether in the store or in the growing state, the mice are really the grand pests of the genus.

All the natural enemies of the genus, whether mammalia or birds, are so formed and so furnished in the covering of their bodies that they come upon them in the most stealthy manner. Not a foot-fall of the cat or the weasel can be heard by the keenest ear; the owl, if it can keep its tongue still, and it "sings out" to rouse and so find the prey, and not to rush upon it after it is found, gets through the air more silently than one current of the air can do when it sets strongly against a counter-current; and this is the reason why the owl is so very successful a mouser. The weasel family are, however, the most scientific destroyers of the whole. The cat catches with the claws, and thus takes hold of any part that it can catch, and it very often sports with the victim before inflicting a wound which is to be speedily mortal. The owl too is a clutcher, whether the original clutch is made by the beak or the talons. The weasels, on the other hand, divide the vessels of the neck by the first and only bite which is necessary for the effecting of their purpose; and this not only with a small animal like a mouse or rat, but with one as large as a hare. In consequence of this "art of killing," possessed by the weasels, they have no equals in those cases where the war has to be carried on against large colonies of mice. One of the chief of them is the taking down of an old rick of corn, either where the base of the rick has not been provided with pillars with caps to prevent the invasion of mice, or where mice have been carried to it in the corn from the field. If this rick is allowed to stand for a few years, the colony produced by a single pair, or one pregnant female carried to it in this way, may be vastly more numerous than any multiplication of ordinary mammalia, under ordinary circumstances, would lead one to suppose. A farmer, by having had mice carried in this way to a rick, the supporting pillars of which are so formed that no mouse can enter it afterwards, and who is not aware of the pest that has been carried there along with the corn, may have full confidence that that rick, carefully thatched above from the weather, is safe as a store against the time of need; but lo, and behold! when he comes to have it cast down, in order to be put under the flail or through the thrashing machine, he finds chaff and cut straw, and hundreds of full-grown mice, and bushels of blind and furless young ones, while the value of his rick is reduced thirty or, in many cases, fifty per cent. On such occasions, it is desirable to have all the cats and curs in requisition, in order to prevent the plague which the rick has fostered from spreading to the other parts of the farm-yard and to the buildings. The cats proceed by ambuscade, and therefore they are not so efficient against the flying multitude; but a good terrier, especially one of the wiry-haired Scotch curs, may be of yeoman service, and will snap here and snap there, finishing his hundreds, apparently quite pleased with the glory of the triumph, and giving himself no trouble about the *spolia opima*, which is the grand object of ambition with the cat. The ferret or the weasel, especially if it has been kindly treated and trained (for if an animal has

activity and *nous* in wild nature, these can always be turned to account by skilful management on the part of man), is the chosen one for this kind of slaughter. It goes where no dog can go, it does its work effectually and quietly, and it is long in being tired. Indeed it appears to be the habit of these singularly active, lithe, scientific in the art of killing, and we may add pretty animals, that the glory of the work appears to be their chief pleasure; and one weasel or ferret will put the seal of death upon a hundred mice without giving itself the least trouble about eating one out of the number.

Interesting as the murine rodentia are, however, we must close our general remarks upon them, and say something about the different species. In doing this, we shall not attempt to enumerate the whole, neither shall we follow any of the attempts that have been made to arrange them into sections or subgenera, because, in many of the species, there is not information sufficient for such a purpose, and even if there were it is very doubtful if it would be of much use to the general student. The technical distributions of animals are, in a great measure, made by the museum naturalists, who are more conversant with skins than with living animals; they are not unfrequently made by them of themselves and for themselves, and therefore they are of comparatively little use in a popular point of view. This being the case, we shall take the species which we mention at random, and under their common names.

THE BROWN RAT (*Mus decumanus*). This species, though now so very numerous in those localities which are favourable to its habits, some of which we have mentioned, is but a recent importation into this country, or even into Europe, or the north of Asia. Considered as a British animal, it is therefore not a native; but, as it was imported without any desire to have it, and rather with the opposite desire, it of course takes its station among our wild mammalia. This species is sometimes called the Norway rat, and it may have been introduced into Britain from Norway, yet it is no more a native of that country than it is a native of the cross of St. Paul's, or the throne of our sovereign lord the king, in the audience chamber, or the house of lords. The animal itself is of course silent on the subject of its migrations; and, as some parts of its progress are quite unknown, the whole falls under that common law of all concatenations, philosophic, historical, or otherwise, that no one of them, taken as a whole, is stronger than its weakest part. Pennant says that it originally came from the East Indies; but Pennant is no authority beyond the scope of his own organs of sight, and perhaps not quite so far; and therefore this part of the subject must be set aside. Professor Pallas is a better authority, though, from the materials out of which he had to furnish qualifications for entering the field of observation for himself, even he is not implicitly to be relied on. His account is that they came to Astrachan in the year 1727; that they came from the western desert, and not from the meridian of India; and the accounts add that they have not yet penetrated far into the *steppes*, or wide arid plains of Siberia. It is not very likely that they should, for their habits with us are any thing but those of animals likely to make plains which are dry for a considerable part of the summer, and covered with snow for the greater part of the winter, the places of their abode. According to the Professor, they came to

Astrachan in formidable numbers; in numbers so formidable, indeed, that no means of resisting them could be found. They had, moreover, to stem the Volga, which is no stinted tide for a river, as the numbers and size of the sturgeons can testify, without any reference to the measurement of its actual dimensions, the length of its course, or the velocity of its current. That they had to cross this majestic river is obvious, from the fact that the city of Astrachan is on the right bank of the river, and the western deserts are on the left; and to have worked round the sources of the Volga in the central marshes of Russia, and round those of the Oural in the mountain ridge which bears the same name, would have been too much for the most migrant rats on the face of the earth, more especially if, according to the Rev. Mr. Ferryman, and the older accounts to which we have alluded, they had led the "disabled and the aged" along with them. Pallas conjectures that numbers of them must have been drowned in the Volga; and this is highly probable, if it can, *in limine*, be established that any of them did cross that river, upon which point we have some doubt. If it was the fact, however, the "disabled and the aged" must have gone to feed the fishes in the Volga and the Caspian. This may be in part, or in whole, the reason why the party that arrived in Astrachan were in such "prime feather," we mean prowess of tail, as that the people of that curious city, though they are made up of almost every people under the sun, were unable to withstand the inundation or the overflow of those canine thickly-serried foes. Into some parts of Europe they came much earlier, though the precise hour of their coming, the country of which they are natives, and the mode of their march has not been ascertained. This is the case in Britain, though they are understood to have made their appearance there earlier than in France. The accounts state that they were first found in ships, and thus it is probable that they have been carried by these to all parts of Europe. This is rendered more likely by the fact that they were first observed in seaport towns, and in the vicinity of the harbours. In such towns they are met with in all parts of the country, even in the extreme north; but there are some inland places which are not yet infested with them, though such places are comparatively few. Their first appearance in France is just as little known; but it is supposed that they were imported, unintentionally of course, from Britain. In Paris the authorities say that they were first observed about the middle of the eighteenth century, but it is probable that they existed in some of the seaports before that time. There are still some of the inland parts of France where not one is to be met with in a whole district, or even in a whole department, thickly as they swarm in other places.

If, as is generally supposed, they have been carried from place to place in ships, we may readily conclude that animals which require so much food, would not land excepting at places where food was to be had; but sea-ports generally are receptacles of garbage; and while the brown rats confine themselves to these, their labours may be accounted useful. Their powers of multiplication are so great, however, that, if they once take up their abode in the sewers and drains opening into harbours, they very speedily extend to other places.

They are properly ground animals, and in those places where the two species of this country are found

together, they are called ground rats or flax rats, in distinction from the black ones, which are roof rats. In towns where they are found together, and they still are so in more places than is commonly supposed, the black rats have their rendezvous in the cock-loft, or above the ceilings of the uppermost rooms; while the brown ones are in the cellars under the lower floors, or in the foundations of the walls, if these are such as they can be worked into burrows. The brown rats make burrows with great vigour and expedition; but not if they can find some ready made. When they are in a house, both endeavour to open for themselves a communication with all parts of it, and especially those that smell of animal matter. The black ones descend between the walls and the plaster, if there is an opening there, or between the two coats of lath and plaster in a partition which is left open in the centre. When this is the case, and the space between the joists are not deafened, the house is very apt to become a rat's palace, where they stride about and squeak the whole night long, so that it is not easy to sleep in any apartment. If a post comes in the way, they set very determinedly to work in cutting through it; and at this they will continue with little intermission night and day; but whether by the same individual, or by successive reliefs, has not been ascertained.

In the neighbourhood of Paris they are exceedingly numerous; and the chief places of attraction for them are those at which worn-out horses are killed; for it does not appear that the French are such great economists of carrion as the English in London. A report of these slaughter-houses and their rats was not long ago made to the French government. The object was the removal of a horse-killing establishment at Montfaucon to a greater distance from the city; and to this it was gravely objected, lest the brown rats, deprived of their accustomed nightly mess of horseflesh, should fall upon the people. It must be admitted that the darings of these rats evinced no small force on their part. Five-and-thirty horses were sometimes slain at this place in a day, and by next morning the rats had made clean skeletons of the whole of them. This it appears is, the way in which carrion is got rid of in Paris; and they have rat holes at the bases of the walls for admitting the nightly scavengers. Dussaussois, who keeps one of these establishments, resolved to surprise the rats at their meal. For this purpose he lodged the carcasses of two horses in an inclosure with high walls; and when he judged that the rats were come in proper numbers, he sent round and carefully stopped all the holes by which they could escape. This being done, he mustered his forces for the attack, each man armed with a torch in one hand and a bludgeon in the other, and instantly they closed the door. The rats fled in all directions from the light of the torches, but from the bangs of the cudgels there was no escape, and the result was the death of a vast number of rats. One single night gave more than two thousand five hundred; four nights more than nine thousand; and though the hunt was only occasional, yet, in the course of a single month, eighteen thousand rats had bit the dust. This was rat-catching on a style which the Parisians might well have termed *magnifique*, and we have nothing to equal it in Britain.

It is said indeed that there are often curious encounters between the nightmen and the rats in some of the subways under the British metropolis. None

of these subways are without rats, and they no doubt contribute to the keeping of these troublesome tenants out of houses. Many of the sinks into which offal, which, however, is very acceptable food for the rats, are such, that a rat cannot find egress from them into the house. The walls and archways are also in general rat-proof, so that the fellows are confined to their subterranean dwelling, which, however, is a very ample and widely ramified one, and its inmates are pretty well fed at all points, but chiefly near the terminations of the smaller drains, which are of course the principal points of attraction. Near the slaughter-houses, markets, and other places, where there is much offal washed into the sinks, the rats are very abundant; and one may better see and hear them through the gratings; but these are generally so placed or formed, as that a rat cannot get up; and the brown rats are not nearly so expert climbers as the black ones.

Thus there is, in those sewers and drainages, which contribute so much to the cleanliness and health of London, a regular permanent population, probably outnumbering the human population above ground many hundred times. This population disturbs or injures very few, it subsists upon what the above-ground population throw away, and in so doing it is useful. Among such a population the regular mortality must be considerable; though there are no means of ascertaining its amount. Very few dead rats are seen however, and those that are seen belong chiefly to the above-ground rats, of which there are also considerable numbers. Even when at the full flood of their discharge in heavy rains, the great sewers of London roll but a scanty supply of dead rats to the river, probably not more, if as many, as the tale of dead dogs, wafted by the open Fleet Ditch alone in the days of Pope. Where they are long, they waft very little animal matter of any kind, so that the floods which they discharge, unless from places near the banks, are far more unseemly than unhealthy. For this we have to thank the rats; and it is of much greater service than those who have not experienced a city with all its refuse stagnating about it, would readily believe. Cleanliness ought to be generally attended to; but still, human cleanliness is only a transfer, not a removal; and if there are not some means of dissipating the refuse, the cure would in time become worse than the disease. In the case of good under-drainage the rats do this, and carry it to the full length of making, among themselves, the maws of the living the sepulchres of the dead; so that they may be regarded as final consumers.

In ordinary states of things, when the sewers are all sound and free, and the weather steady, matters go on with great regularity, and not with more noise than might be expected among animals so ready to fight, either for love or glory, as these rats are. But when a heavy rain comes on suddenly, the rats are put in motion, and the effect of it upon them may, in part, be compared to that of the setting in of the seasonal rains in the warm countries. It puts them in motion, and makes them scamper about; but it brings an additional supply of food; and if the brown rats have plenty to eat, they are not very particular as to lodging. Although not absolutely aquatic, they prefer places near water, are expert swimmers, and not liable to be easily drenched with wet. When the nightmen get into the sewers with torches, the first rats they get sight of generally retire before the

light; but as they proceed, and the numbers accumulate, the rats at last make a stand, and fight desperately. The fight is said (for few see it), to begin among themselves. The party which the light drives up the sewer, are mistaken by the others into whose natural territory they have come, for invaders that have hostile intentions. The tocsin is accordingly sounded, and the natives muster *en masse*, and bearing to the point of attack; between their fear of the torches, and the fact of having no hostile intention, the brown rats are deprived of stomach for fighting their fellows, and so they turn; by this means the whole of the rats are turned toward the human invaders; and though their proper object is in all likelihood merely that of getting past the men, and so escaping, yet the men are said to be sometimes overpowered by numbers, and fairly put to the rout, though the return of the killed is always in the muster-roll of the rats only.

In places where there are no archways for the habitations of these rats, and which yet afford subsistence for them, they often do considerable damage by their excavations. They often undermine the foundations of granaries and store-houses, of manufactories which abound in offal, and of mills; and in the last case they sometimes mine through the dams of the ponds and let out the water. The Parisian horse-killing places are those at which the greatest number have been observed; and there the supply of food is so abundant and so tempting, that they have worked some of the adjoining grounds full of holes like those of a rabbit-warren. This has been done to such an extent, that the surface has, in many places, fallen in; and the distant colonies have made regularly beaten paths from their habitations to places where they find and feed upon the carrion during the night.

They are always apt to accumulate about places where animals are kept, though they do not always lodge in such places. Menageries always have a smell of carrion about them, however clean they may be kept, and, having this, they are sure to attract the brown rats. The Zoological Society of London feel this in their gardens at Regent's Park, which are visited at night by rats from the other side of the canal. Of course they do not offer battle to lions and tigers, or to any of the large animals; but they destroy the small ones, especially the young of guinea-pigs. In poultry yards and preserved grounds they also commit considerable depredations on the eggs and the young birds. Of grain, they are perhaps not, upon the whole, quite so destructive as the mice, and their depredations are not so well seen, as they do not inhabit the ricks, and barns, and bins of corn; but they plunder during the night, and carry off considerable quantities to their subterranean abodes.

Their personal appearance does not require much description, as there are few persons, especially about towns and other thickly inhabited places, that have not opportunities of seeing a brown rat. It is the largest of the genus to be met with in Britain, being, in full grown ones, fully ten inches long in the head and body, of which the head occupies nearly two and a half. The ears are about two-thirds of an inch long, which is less than the length of those of the black rat; the tail is also shorter in proportion; and both they and the muzzle are nearly naked; the tail is annulated with the scaly plates of epidermis, already noticed as being general in the genus; these are without any fur; but there are a few short and scat-

tered hairs between the rings; the upper colour is greyish brown, and the under colour whitish grey; the body is thick and strong; and the expression of the animal is a mixture of cunning and sulkiness. Common domestic rats, especially when young, are hardly able to master these rats; and when they muster in numbers, no cat has any chance with them. There are many instances mentioned in which a cat has been turned into a cellar full of these rats, and been almost instantly killed and eaten by them. Dogs, especially terriers, succeed much better; as they bite with a snap, and dislocate the spine of the rat at a single pinch. If the dog is not staunch, however, and one rat fastens on his nose, he is not very fond of attacking another.

THE BLACK RAT (*M. rattus*) is sometimes called the "old English" rat; but the epithet does not appear to be very accurately applied, as the fact of its being a native of Britain or even probably of Europe, is doubtful. The question of its actually being an imported animal is not so completely settled as the same question is with regard to the brown rat. No mention is made of it by Aristotle, or by any other of the naturalists of antiquity. Conrad Gesner of Zurich, who wrote about the middle of the sixteenth century, is the first author by whom it was noticed; but the mere fact of his being so does not prove that the animal did not exist in Europe before then. Wherever the rats had their original habitation, it is probable that the great intercourse by shipping would carry them to all places to which the ships reach. There is hardly such a thing in the whole navies of the world, as a ship with no rat in it; and, accordingly, the ships of Britain have carried both rats to every part of the world that they have visited. In no place, however, do they appear to disperse themselves very widely in wilds of nature; for though they may be said to be at war with man, they are never far from his habitation.

In all situations the black rat may be considered as a house-rat, generally quiet during the day and active during night; but it is not seen in the fields, neither does it burrow in the ground. Stables are favourite places for it, and it does not hesitate to take up its abode in a cellar; but it prefers a dry one, and lodges in a hole of the wall rather than the flue, unless the latter is very dry.

It is very considerably smaller than the brown species, for it seldom measures so much as seven inches and a half in length; and though its muzzle is larger, its head altogether is shorter. Its ears are also larger and rounder, and its tail is larger than its body, while that of the other is not so long; the ears and tail are naked; the eyes rather large; the fur on the body shaggy; the whiskers and tufts of stiff hairs over the eyes very long, and the whole expression more rough and fierce than that of the brown rat. It is also more rapid in its motion, and a better climber; but whether it enter the water so readily may be doubted. The colour is black, with a tinge of grey above, and ash-colour on the under part, often whiter on the breast and throat. There are apt to be occasional albinos, however, both among these and among those of the other species; and it is said that those which are of the natural colour expel the albinos from their society, or, more strictly speaking, withdraw their society from them.

Advantage is taken of this for the purpose of effecting the expulsion of rats from houses infested

with them; but whether it does or does not produce the effect, we pretend not to say. If a rat is caught it is rolled in flour, fine meal, or powdered whiting, until its colour is completely changed; and then it is sent forth to its companions, who are so suspicious of its appearance, that it fairly chases them out of the house. A singed rat is often turned lame with the same intention; but whether either mode produces any effect is not fully ascertained. Rats are, however, very wary animals, and shy of strange appearances. They also often desert one house suddenly and go to another, without any very obvious cause; and when this happens, soon after one of these supposed modes of expulsion has been put in practice, the departure is sure to be ascribed to that. One half of the incantations which are resorted to have been established by being antecedent in time to other unconnected events, the real causes of which were not known. The Welsh have one for the supposed expulsion of mice. They roast a live mouse to death before the fire, in firm belief that the smell frightens away the others, which is the very antipodes of the effect which it would have, if it had any effect at all. There is an American rat, which has been considered as a species by Rafinesque, Dr. Harlan, and others; but it differs from the common British one in nothing except in being duller in the colour.

The rats of foreign countries are pretty numerous; but very little is known of their manners; and it is not easy to say which is a rat and which a mouse, that being more a difference of size than anything else. It is generally understood that the mice are less fond of animal matter than the rats. But the chief difference appears to lie in the rats being able to kill larger animals than the mice. The teeth, which afford the best criterion of the disposition of an animal, are exactly of the same structure in the mice as in the rats. The incisors furnish a pair of gnawing instruments, as in all the rodentia, and the cheek teeth have their crowns with tubercles covered with hard enamel.

THE SUMATRA RAT (*M. Sumatrensis*), is an inhabitant of the island after which it is named, and probably most of the neighbouring ones. It is also not uncommon in some parts of continental India, and is met with as far to the north as Bengal. The most remarkable of its external characters is its size, which is about equal to that of a common rabbit. The body and head are, together, nearly fourteen inches long, and the tail is about the same. In its general appearance, and also in its colour, it resembles the brown rat more than the black one; but still there does not appear to be sufficient reason for supposing that the brown rat is the same species, diminished in size by being brought into a colder climate. The Sumatra rat is dull brown on the upper part, greyish on the under, and black on the legs and feet. The tail is very thinly covered with hair, but not quite so naked as the tails of our rats. It frequents the neighbourhood of houses, and burrows under the fences of gardens, or the walls of huts.

THE CARACO RAT (*M. Caraco*), is a Siberian species, inhabiting the easterly parts of that extensive country, where the brown rat does not appear to have yet made its way. It is about the same size as the brown rat, and not very unlike it in form; but the colours are not the same. But the upper part is a mixture of reddish and dark grey, becoming paler

on the flanks, and passing into whitish ash on the under part, and also on the feet. It is found near the habitation of man, and, like the brown rat, it likes to be near water. The tail is very little more than half the length of the body; and the half-webbed feet show that it is an animal well adapted for swimming if occasion requires.

THE ALEXANDRIAN RAT (*M. Alexandrinus*), is in some respects the very reverse of the one last mentioned. It inhabits dry places in Egypt. The upper colour is reddish grey, with the hairs on the back flattened, broader at the middle than at either end, and striped on the one side. The under parts are ash colour. The tail is one-fourth longer than the body.

THE ICELAND RAT (*M. Islandicus*). Even Iceland, cold as it is, and remote from any other land, has its peculiar species of rat. It is grey, with the exception of the back, which is blackish, and there are some yellowish spots on the flanks. The tail is rather longer than the body, nearly naked of hair, but marked with numerous rings of scaly plates on the epidermis.

There are various other rats named in other parts of the world; but as very little is known of their manners, and the little that is known resembles the manners of the rats of this country, they have not much attraction for the general reader. The distinctions of them, as museum subjects, are also a little confused, as the very same species appears to have got two or three different names, from the different authors that have described it. Some of those which have been named rats, are also not true rats; for they both want the tubercles on their claws; and the animals are of course more vegetable in their feeding, and less disposed to haunt houses, or reside in the close vicinity of them. These are the characters which we associate with the name rat, and therefore it were as well that it should be confined to such animals; at least, if that were done, the name would be more expressive of the characters. Of these true or carnivorous rats there do not appear to be any which are more aquatic in their habits than the brown rat; and though that prefers situations near the water, and can swim, it cannot with much propriety be called an aquatic animal. Therefore, in strict language, there is no such animal as a "water-rat."

We shall now notice a few of the leading species of the mice, which, as we have said, have still the same character in the cheek-teeth as the rats, only they are smaller and less powerful, but certainly not less mischievous, than their congeners. They are also more widely dispersed than the rats; for, though "the mouse," which is the typical animal, comes more into the dwellings of man than any other species of mammalia, yet there are others which keep more to the fields or the woods.

Mice have been known from the earliest times; and they appear to have been peculiarly numerous in the early ages. While heathen temples were in use, and sacrifices offered, they held out powerful attractions to mice; and when the gods of Olympus are holding a sage council as to what part, or whether any part, they shall take in the war between them and the frogs, Minerva is made to break out in a tirade against them for gnawing her web on the loom and nibbling her sacrifices on the altar. Polytheism thus appears to have been a mode of worship well adapted to the mice; and the temples appear

to have been fine and fat pastures for them, at times when the larders of the people were not so well stored as they are at the present day. Matters are now much changed for the worse to mice, and the better to men; for a "church-mouse" has become the current name for leanness and poverty. Yet mice are still not unfrequently met with in churches; and in a country church a mouse may sometimes be seen on the canopy of the pulpit looking down with wondering eyes on the congregation. They meet with more food in such places than one would at first suppose. Mice are very insectivorous, and capture and eat great numbers of flies and beetles, of which there is usually no lack about churches. Thus, in spite of the universality of the proverb, a church-mouse is really not that starveling which it is called.

The name mouse, which, though differently pronounced by the several nations that use languages derived from the same stock as the English, is the same as the Greek name, and that name is from the active form of the verb "*to hide*," and means that which hides itself. The Highland name *luch* is nearly the same, but can hardly be rendered: "that which whisks into holes" is something like the meaning, but not the whole of it. The French name *souris*, and the Italian *sorice*, are obviously from the Latin *sorex*, which does not mean a mouse at all, but is the name of the shrews, which are carnivorous animals, having all the three kinds of teeth, and of course of a totally different order—though the shrews have very improperly been called mice.

THE COMMON MOUSE (*M. musculus*). Though a very mischievous little creature, the common mouse is very pretty, and nothing can separate it from the human race; for, let man migrate where he will, the mouse is sure to accompany him, and to share in all his provisions, if it can. The only other animal that has been an equally constant attendant upon man in all his movements is the common house-fly, which serves in part as food to the mouse. Every house and every out-house has mice in it, and wherever the mouse is found the fly is found also. It is the mouse that has led to the domestication of the common cat; and were it not for cats, mice would so multiply in houses as to be intolerable. The mouse is a timid animal, but it can be tamed without much difficulty; and it never displays any of the ferocity of the rats. The taming of mice is, however, rather their consenting to be fed and fondled, than any taming in the proper sense of the word, any calling forth of a proper propensity. Propensity of this kind they have none, for they are not social in any one part of their own economy. They of course pair in a temporary way, but the pair have no attachment to each other. They breed many times in the course of the year; and as they are always in shelter, they breed just as freely in the cold season as in the warm. The breeds are not quite so numerous as in some of the rats, but they breed more frequently in the course of the year; six or seven is about the average number in a brood; and as all the genus come into the world blind and naked, the mother prepares a warm nest for their reception. If they are supplied with food, they continue to live and breed away "in shoals and nations," without coming abroad, or seeking to change their quarters. Aristotle ascertained this fact by the actual experiment of enclosing one gravid female in a vessel of corn, and

carefully preventing all other mice from entering, and it was not very long till he found that he had a colony of six score; nor is there any doubt that they would have gone on until the whole corn in the vessel had been converted into mice, after which they might probably have eaten each other up to the last mouse, though certainly not to the cannibalism of the Kilkenny cats, which, in the course of one single night, ate each other, except "the two tails and a bit of claw." Six weeks is understood to be the whole length of time necessary for enabling the young mice to find their subsistence independently of any attention from the mother, five-and-twenty days of which is occupied in the gestation, and the remainder in the nursing. At what age they become fertile is not exactly known, but it is understood to be at a very early one; and it must be so, otherwise Aristotle would not have obtained 120 in a short time.

Farmers often discover the fact of this rapid increase without wishing for it. If one rick of corn is left in the stack-yard, and all the rest of the crop disposed of, so that the barns, houses, and grain-lofts, are empty, then the whole mice take up their abode in the unfortunate rick, if it is not so built as to prevent their having access. There they are quite at home; and though they are not much seen outside, or much heard, except by their feeble chirpings — by the way, there is no word in English expressive of that class of sounds among which the voice of the mouse may be reckoned. It is not "chirping," and it is not "whistling," but something between the two. The Scotch word *cheeping*, as distinguishing from *whaeeping*, which means short whistling, does it exactly. They are, however, not the less busy on that account. They do not disfigure the outside of the rick, but they sometimes, notwithstanding, reduce the whole of the inside to chaff, and put one in mind of the white ants, and other insects of warm countries, which, working in the dark, unheard and unseen, reduce the whole interior of a tree to powder. The length of the common mouse, when full grown, is nearly three inches and a quarter in the head and body, of which rather less than one inch is occupied by the head; the tail is nearly three inches in length, and the ears, which are oval, are nearly half an inch; the fur on the back is of a peculiar brownish ash, technically known as mouse colour, and the under part is pale ash; the ears and the tail are covered with heavy short and soft fur.

Though the colours which we have mentioned be those in which the common mouse is most frequently seen, yet it is subject to some varieties, and also to albinism; and it is a curious fact that the albinos are based in a variety, the pure white colour and the red eyes being transmissible from generation to generation. This does not, we believe, take place in a state of nature, for the "white mice" are all bred for being kept in confinement as curiosities. The "manufacture" of them, so to call it, was begun in Italy, and they are still carried about in little cages or tread mills by the beggar boys from Cisalpine Italy, of which such numbers infest our streets, and are so cruelly used by the wretches that make a most iniquitous gain of them and their mice. It is not a little singular that northern Italy, the valley of the Arno chiefly, should have been the place where an albino variety of the common domestic ox was bred, and that the small remain which yet exists in England should retain in great part the white colour.

THE LONG-TAILED FIELD MOUSE, or WOOD MOUSE (*M. sylvaticus*). This is one of the most abundant and most mischievous of all the mice; it does not come into the houses like the former species, but out of doors it is here, there, and every where, and always doing mischief to every kind of vegetable and vegetable substance which it can injure.

It is half an inch longer than the common mouse in the head and body, and another half inch in the tail; the ears are also larger, the eyes larger and more prominent, the muzzle darker, the whiskers very long, the feet well adapted for running, the fore ones for grasping and the hind ones for leaping. It is a very pretty little animal, gentle in its disposition, and though very timid in a state of nature it readily bears confinement. The upper parts are yellowish brown, inclining to blackish on the back; the under part is greyish white, with a yellowish spot on the breast; the hairs on the upper part are annulated, being grey at the base, yellowish in the middle part, and some black, others reddish at the tips. It is an exceedingly swift-footed animal for its size, and runs about with wonderful celerity. It is very prolific, having certainly two litters in the year, and probably four, each of which averages about eight. It is a burrowing animal, unless it can find sufficient cover under low and closely-tangled bushes. It is a clever excavator itself, but it sometimes avails itself of the runs of the mole, especially in winter, at which time they are deserted. In its retreats under ground, and sometimes under a bunch of moss which it collects, it stores up the plunder of the fields, which plunder it takes in large quantity. If ricks of corn are left in the fields, this mouse is as apt to enter them as the common mouse is, and it is as often found along with the common mouse in farm-yards. In gardens and nursery grounds it is especially destructive, and every means that can be thought of for destroying it is put in execution. All will not do, however; the mouse returns to the charge, and the watchfulness of the gardener is never at an end; he has a good many fellow labourers too in the destruction of this mouse; the owls are among the most efficient of these, and as such ought to be encouraged about gardens and nurseries. The kites lend a hand, but they are shy of coming so near, and the weasel tribe are conducive to the same end; even the hog helps to carry on the war against this mouse. It does not, it is true, eat the mice themselves, but it, according to Pennant, roots up their hoards of provisions, and thereby mangles and disfigures the surface.

Another formidable enemy of this mouse, and of all the small rodentia that frequent wooded places, is the common wild cat. There are certain seasons of the year when the mice get very abundant and fat in the copses, and where the cats capture them in great numbers. This is chiefly in autumn, and the best places are the hazle copses in remote situations, where few people go to gather the nuts; these fall when ripe, and at this time the mice throng to the copse, dig their magazines, and instantly set about storing them with this favourite food; the cats are there in force also, and keep yelling the whole night long. It is not over pleasant to come upon them at those times. All the feline race are sulky while feeding, or even in the anticipation of feeding; and as the cats among the mice in the wild copse may be said to be upon their own ground, and killing their own mutton, they are not fond of budging, and will

sometimes spring. Now, though a man can of course master a wild cat without much difficulty if he goes the right way about it, he may get an ugly scratching. The best mode of dealing with the cat is, therefore, either to keep out of its way, or to be the first to attack, for unless it springs it is not very formidable. There are sometimes other rodentia in the same copses along with this mouse, the field mole for instance, and sometimes the dormouse, though the dormouse may be looked upon as rather a scarce animal in the copses of the northern glens, where the cats are very plentiful as well as fierce.

THE HARVEST MOUSE (*M. messorius*). This is the only other species of true mouse, that is, of mouse with tuberculous cheek teeth, that occurs in Britain; and hitherto it has been met with only in the south of England, at least not farther to the north than Cambridgeshire. As a British animal it was not known till discovered by White, of Selborne; but it has been much longer known on the continent, in many parts of which it is not rare. It occurs in Germany, in Poland, and Russia, and also in Siberia; but it appears to have, like some of the other species, been called by a great number of names.

It is the smallest of British mammalia, and indeed among the smallest of the whole order. The head and body are two inches and a half in length, of which the head occupies about five-sixths of an inch; the ears are shorter in proportion than those of any of the other British mice, being only a quarter of an inch; the tail is a very little shorter than the head and body, so that the total length of the animal is rather less than five inches; the body is more slender in proportion to the length than in any of the others, and the whole weight is not more than a quarter of an ounce. The tails of all the genus are capable of a good deal of motion, and contribute not a little to the steadiness of their direction when they leap, which they are understood to do when they catch insects on the wing. The tail of this one, however, is prehensile, and so used by the animal when it climbs the cusses of corn in order to feed on the grains, or the milky juice of the young grains at the top. Its summer residence is chiefly in the corn-fields, where it is supposed to feed upon insects until the grain is ready; in winter it either burrows to a considerable depth, at which it remains torpid, or it gets into the shelter of a rick of corn or some other place, where it can find both warmth and food, and in such situations it continues active, carries on its breeding, and knows no winter. It does not appear that it carries much provision to its under-ground retreats, in which it becomes dormant.

It is a very pretty little creature both in its form and its colours, and it is quick and lively in its action, and capable of undergoing a great deal of fatigue. The colour of the upper part is bright reddish brown, produced by the different colours of the basal and distal parts of the hairs, the basal parts being dusky black, and the terminal or distal parts brown. The under parts are pure white, and the upper and under colours do not pass gradually into each other as they do in many of the genus, but meet at a well-defined boundary.

The nest is not under or even on the ground, but suspended to the stems of the corn, and is a very pretty structure. The annexed cut will give some idea of the external appearance of the nest, and the relative size of it and the animal.

This nest is constructed in rather a laborious manner, wholly of vegetable materials, but varying with such as can be most readily obtained. It is about half a foot from the ground, and, in most cases, fastened to the stems of living plants. It is in the shape of a round ball, neatly woven with vegetable fibres, which the animal appears to obtain by splitting the long leaves of the corn and other plants of the same family with its teeth. These are matted up, with husks and other short substances, until the nest is very compact. The nest appears to be so constructed, that it can by its elasticity accommodate itself to the number of young that may happen to be in the litter, and also to the increase of the edge as they grow. The young vary from four or five to nine or ten; and the nest is made very smooth inside for them; and they always appear completely to fill it, whatever may be their number. The entrance to the nest is by a small aperture in the side, which partially opens and shuts, in consequence of the elasticity of the structure. The manner in which it goes to work in the constructing of this nest is of course not known; but the fore paws of the little animal are what may be called very "handy;" and the prehensile tail must enable it to have full command of them in working, which is probably one of the chief uses of that peculiar instrument; though it may also enable the mother to support herself while she suckles her young, as it does not appear that she can very easily get into the nest along with them. Much of its domestic economy, however, is, and we fear must always remain, matter of mere conjecture, of which the accounts that are given in writing will vary with the discretion of the writers.

Though a very timid and delicate little animal, the harvest-mouse will not only live, but breed, in a state of confinement; only it requires a good deal of exercise, and should be provided with a little tread-mill in its cage, to which it does not require to be sent, as it appears to like the exercise. But, notwithstanding its diminutive size, its handsome form and its beauty, it shows the disposition indicated by the tuberculated cheek-teeth. When the female produces young ones in captivity she often eats them, and flies, especially bluebottles, excite the desire for animal food. If they come near its cage it springs at them with its fore paws extended, much in the same way as one may see a cat doing when engaged in fly-catching on a fine day. The preference given to these above any sort of vegetable food is a decisive proof of the general habit of the animal, and renders it highly probable that, as we have already hinted, the summer food consists in great part of insects. As is often the case with the field-mouse, the harvest-mouse is carried in the sheaves of corn, and often produces a considerable progeny in the rick or the mow; and in proportion to its size, it is by no means the least destructive of

the mice which harbour and breed in such places. In the early period of its history as a British animal, and when it was accounted rare, the harvest-mouse attracted a very considerable share of attention; but, since it was found not to be very rare, though it is rather local, the novelty has worn off, and it has taken its rank among ordinary mice—that is, as being withal a pretty and lively animal, but under particular circumstances a very amusing little pest.

As there are three distinct species of mice with tuberculated teeth in Britain, and only two of rats, it might be inferred, *a priori*, that the species of such mice, taken altogether, are more numerous than those of rats. This is the case; and though mice do not muster in such numbers at particular points as some of the rats do, yet they are distributed into more places, and are altogether more numerous. They are found in very many parts of both continents; but little is known of their manners. The accounts which are given of them would, however, lead us to believe that they are field or forest mice; and that there is no mouse really a household one, and accompanying man in all his movements, except the common mouse with which every one is so well acquainted. We shall merely name one or two of them, without vouching for the perfect accuracy of the nomenclature.

THE SUBTLE MOUSE (*M. subtilis*) is a native of the central and northern parts of Asia, and there appear to be some varieties of it differing from each other in some of their habits. They are small animals, not exceeding three inches in length in the body, but the tail is rather more than that; the colour is yellowish ash, with a black dorsal line; the ears are in folds; any variety of this has the fore-paws very large, and is dexterous in climbing trees; their structure has not, however, been examined with the care necessary to fix their place; and it is probable that some of them belong to the section which have no tubercles on the crowns of the cheek-teeth, and are in consequence much more vegetable in their feeding than the true mice which have the teeth tuberculated in the manner of these that have been already noticed. In the American continent, especially in South America, there are a considerable number, some of which are called rats and others mice, but nothing interesting to ordinary readers is known of them, and, therefore, we shall not farther extend the list.

We shall now very shortly advert to the species which have not the cheek tuberculated, which are in consequence chiefly vegetable in their feeding; and our notices shall be chiefly confined to the British species which have, of course, the greatest attraction for the readers of the "British Cyclopædia." We gave a very slight notice of them in the article ARVICOLA, from that we referred to the French name CAMPAGNOL, as we had then intended to go fully into the details of all the species of the mammalia. But finding that, with any thing like justice to the other parts of nature, that would have swelled the size and price of the work to far greater extent than was consistent with its object, and that a very considerable portion of these details, being purely of a technical nature, could have no interest whatever for general readers, we have not only felt it necessary, but judged it for the best, to omit several of the articles referred to in the early numbers, and, among the rest, the intended article CAMPAGNOL, and place the substance of what relates to the British species here.

The larger species of these animals have got the

common name of rats, and the smaller ones of mice; and among scientific naturalists they have occasioned no small degree of perplexity. Linnæus classed them with the beavers. They agree with the beavers in some particulars, but differ so much in others, that they cannot be classed with the typical or building beaver; because they not only want the peculiarly formed tail of that animal, and have none of its habits as a builder, but have the teeth different—the beaver having four cheek-teeth in each side of each jaw, and the animals in question only three, in the same number as the rats. Their cheek-teeth have the crowns flat, or without tubercles, and only roughened by zig-zag lines which cross them. This indicates that the food is chiefly vegetable; but the smaller number of teeth shows that it is of a less stubborn nature than the bark and twigs upon which beavers subsist during the winter. The teeth are like those of the musk beaver of Canada (*Fiber*); but the feet are different. That animal has no webs to the hind feet, as the true beaver has; but the edges of the toes are beset with stiff bristly hairs which appear to answer the same purpose; but in the animals under notice, even the aquatic ones, which are very expert swimmers and divers, there is neither web nor margin to the toes. It does not, therefore, appear that any real advantage can be derived from the grouping of these animals with any other genus; but that they assimilate so equally to different ones, that the best way of dealing with them is to take them singly by themselves. They are all burrowing animals, which collect in their burrows a store of provisions for their winter support; and therefore we may conclude that they do not become dormant, unless where the winter is excessively cold.

There are three British species, one inhabiting the banks of streams and small rivers, another found in the sides of ditches and under hedges, and the third more generally distributed over the breadth of the fields. The first of these, and by far the largest of the British species, is,

THE WATER RAT, or rather WATER VOLE (*A. aquatica*). This is a very common and well known species, being found by the banks of every stream and rivulet, where these banks are not rock, or sand, or gravel, or some other substance which will not admit of a human being under. The opening to this burrow is never very far above the level of the water, or, if that level is subject to variations from floods, there are generally two openings, one higher and the other lower, but not the one immediately over the other. The lawn, or bit of grass in front of these openings, is generally kept cut very close and neat; but what may be the object it is not easy to say. The higher opening answers another purpose besides that of enabling the animal to adapt itself to the height of the water. It is the passage from which the landward part of the pasture is reached. As the water-vole always takes to the water when alarmed, one would be apt to suppose that it found the whole of its food in the water. But this is not the case. It is a vegetable feeder, and the fleshy and bulbous roots of plants form the chief part of its food. Of these it obtains a good many in the water no doubt, but they are still more numerous on the soft and moist meadows and borders, especially where, as there often is, a stagnation of water behind the immediate bank of the stream. These little accumulations of stagnant water have generally many plants about

them with fleshy roots, and thus find the water-vole in plenty of food, both for summer consumption and winter store. Even in these places, however, the burrow is in the bank of the running stream, and not in that of the stagnant water.

These animals stand accused of having predatory and even sanguinary habits, of eating worms, the fry of fishes, and even the young of aquatic birds. This is wholly unfounded; and it is either a mere analogical reference drawn from the fact of the animal being called a rat, or it has been confounded with the brown rat. The brown rat is, however, always nearer habitations than the water-vole, as it is constantly on the hunt for animal refuse, which the other does not eat, but contents itself with its meal of roots summer and winter.

The water-vole is intermediate in size between the brown rat and the black one; but the tail and ears are much shorter, the fur finer and closer, and the whole expression of the animal more soft and innocent. The shape of its head and muzzle, and the total absence of every thing like a harsh line in the whole of its contour, would induce one who knows any thing about the agreement between the expression and the disposition of animals, to set down the water-vole as one of those gentle rodentia that would not, under any circumstances, hurt a worm or any other thing having, or ever having had, animal life; and it is one of the cases in which the expression and the fact are remarkably true to each other.

As usually found in the richer parts of England, the water-vole is about eight inches and one-third in length in the head and body, of which the head occupies about one inch and five-sixths. The ears are less than half an inch in length, and almost entirely hidden in the fur. The tail is about four inches and two-thirds, being thus a very little more than half the length of the body. The head is short, rounded in its outlines, and the muzzle is blunt, the nose not indicating that keenness of scent which is possessed by the rats. The incisive teeth are yellow in their anterior surfaces, chisel-shaped, not unlike the fore teeth of the beaver. The body is also thick, but part of the thickness is made up of the very closely-set fur. The tail is not naked like those of the rats, but has fine short fur on the upper surface, and pretty long hairs on the under. The fur on the flanks is pretty long, and so it is on the upper parts of the legs. The fore feet have five toes completely formed, and a rudimental thumb consisting of a single phalanx. The hind feet have five toes all fully developed, not webbed or margined, but connected by a small membrane at their bases. The fur is of that shining character which has, in the hairy animals, a strong repulsion to water, so that it does not get matted or even wet when the animal is under water. The colour of the upper part is a mixed brown, having both a reddish and greyish tinge; and the under part is grey, with a yellowish tinge in some individuals, and a greyish in others. When the animal is alarmed, by any one treading heavily over its burrow, or surprised on the trimmed grass at the entrance, and makes, as it does in all cases of alarm, its escape into the clear water of a pool, it presents a very pretty appearance. The rapidity with which it gets to the bottom of the pool causes it to take down with it a considerable portion of air in the fur. This collects into little bubbles, without being detached, and the creature appears as if, by going into the water, it had got its

jacket spotted over with pearls. But, though it takes to the water as a means of safety, and gets down till it is quite submerged, it has not the same power of continuing below, as the otters and other mammalia which prey in the water. It must very soon come up to breathe; but if the cause of alarm continues, it puts up only the point of the muzzle, and cannot very readily be seen.

It is found in all parts of Britain, and also of continental Europe, where the waters and their banks are suited to its habits. It does not indeed occur on the more elevated of the mountain rivulets, or where the heath comes down to the edge of the water; but it occurs as high as there is a sufficient supply of fleshy roots to be had. It is always most abundant where the banks are of a rich and loamy character, and on some of the trouting streams it is often a considerable annoyance to the angler. Not that it does any active harm either to man or fish, for it is at perfect peace with the whole animal kingdom; but the angler frightens it; it enters the water with a plunge, and thus frightens the trout; and, once alarmed, they are angled for in vain.

There appear to be some varieties, probably climatal ones. That which we have described seems to be the one of low-lying and rich places; and when a greater elevation is gained, and the climate colder, the size is smaller and the colour different. In the upper part of the valley of the Rhine, a variety is known locally by the name of "Schermmaus," and called the Strabourg mouse (*A. terrestris*, Linnæus). This one is only six inches long, with the tail one-third of the length of the body, and the ears almost entirely concealed in the fur. The colour is dusky grey, more or less black, and sometimes entirely black on the upper part; and there is a whitish trace on the sides of the mouth. It is very probable that this is the upland variety in many countries, and in Britain among the rest, and some colour is given to it by the fact that the Alsatian name of "Schermmaus," altered in the pronunciation of course, is in common use in some of the midland parts of Scotland. They pronounce it "Shear-mouse," and probably give it that name on account of the neatness with which it keeps the grass shorn at the entrance of its burrow. Its colour is dusky grey, more or less blackish, and it is smaller than the water-vole of the lower and richer parts. This shear-mouse is chiefly found on the smaller branches of the rivers, after they so far leave the hills and moors as to have rich banks; and we are not aware that there is, in these situations, any water rat of a reddish-brown colour, though the shear-mouse is very abundant, and a subject of alarm to the infant poachers who grope for little trout under the banks. We never heard of a bite being inflicted by the animal, though rustics speak of it as being capable of dinting a spade with its teeth; but as they say the same thing of the eel, if it happens to be of more than ordinary size, it signifies not much what they say. Lower down, in what may be called the final valleys of the rivers, and in their effluents that come through the rich fields there, the water-vole is larger and brownish, and gets the name of water-rat; and if we remember rightly, there are some places between the localities where both animals may be met with. Their habits are very much alike, only we are inclined to think that the larger and brownish ones prefer broader, stiller, and deeper water. We are much in want of a good natural history survey of the whole

course of some of those rivers which rise in the most elevated, bleak, and barren places, and flow through all varieties of soil till they meet the sea in the very richest. The Tay is the preferable river for this purpose; but years would be necessary for the proper examination of it. Until such surveys are made by competent persons, untrammelled by any preconceived theory, the natural history of our river animals, few as they are, in so far as the mammalia are concerned, must remain very imperfect. This species is known to the Highlanders; but they have not an original Gaelic name for it. They call it *radan uisg*, which is the Gaelic for "water-rat."

THE BANK VOLE (*A. riparia*) is a much smaller animal than the former, and not so aquatic in its habits. It lives much under covers, and, on account of this, and of its small size, it is but rarely seen. There has been no very good description of its habits published anywhere, and, as a British animal, it has been known only during a very few years, and it is still known only as rare and local. Ignorance of the existence of a rodent animal may be in general taken as a presumption, though not perhaps as an absolute proof, that it is harmless. This species was first observed in Essex, in the year 1852, by Mr. Yarrell, and it has since been found in various other places, but always on the low and rich grounds. It may have often been seen before this, but mistaken for the field or meadow species, which are very abundant. To a cursory observer they are not unlike each other; but this one is smaller, more feeble and contracted in the anterior part of the body, and has the ears more conspicuous, and the tail larger—considerably larger. The habitats are different too, at least in so far as the localities of this one are known; for the common field-vole does not reside chiefly about hedges and ditches, but rather in the meadows; and, according to Mr. Yarrell, this one uses wool and other animal fibres in the construction of its nest, while the other uses vegetable substances only. The colours are: rusty brown on the back, ash colour on the sides, and white on the under part; the tail is dusky on the upper side, and whitish on the under. The tail is slender, but it does not taper to a point like the tails of rats, and it is a little bushy at the end. The dimensions as given are: the head an inch long, the body two inches and a third, the tail an inch and two-thirds, and the ears rather less than half an inch. There is every reason to believe that this species is pretty generally distributed in the warmer parts of the country, and that the low siffling noise that we so often hear under hedges and low creeping brakes on fine days is its cry. It is probable also that some of the little foot-prints that are made in the snow under hedges are made by this animal.

FIELD VOLE (*A. agrestis*). This is the short-tailed field mouse, the meadow mouse, and various other names; and, though it is not a true mouse, all the epithets are applicable, as the animal ranges in all these places; and sometimes comes upon a locality in such an overwhelming flood of numbers that, small as it is, the damage which it does would be altogether incredible, were it not known and felt in such a way as to leave no room for scepticism.

It is a burrowing animal, and takes up its winter quarters either in a burrow of its own digging or in the deserted run of the mole. In summer it lives and often nestles in the tall and coarse herbage by the sides of ponds and morasses in meadows; and at

this season it is but rarely found upon very dry grounds. The reason why these do not suit it is easily seen: at all times it prefers fleshy and pulpy roots to every other kind of food; and they form its chief subsistence during the summer, though when the grain is matured in the fields it pays them a visit also. The favourite roots are both most abundant and most easily dug out in the soft grounds, and this is the reason why the animal prefers these. The nest is constructed entirely of vegetable fibres, and the number of the young at a litter averages about six. The animals are exceedingly voracious, and so impatient of hunger that they have been known to eat their own species in cases of extremity, though, if they can procure vegetable food, they never touch an animal substance.

The length of the full-grown field-vole is rather more than four inches, exclusive of the tail, which is about an inch and a quarter. The ears are not half an inch long, and the tips of them just appear above the fur. The thumbs on the fore-paws are mere rudimental tubercles, without the slightest vestige of nails. It is found in most of the lowland places of the British islands, and it is not uncommon in the Orkney isles, where the water-vole does not occur; but it is not found in the mountains. It is in fact strictly a champaign animal, frequenting meadows and gardens, and the fields generally according to the seasons. Its depredations in the corn-fields are not very different from those of the field mice, so long as there are grains to be found; but when the animals are in numbers, they are apt to pass to the autumn-sown crops, and completely clear them roots and all. In gardens they are also peculiarly destructive, not only by eating seeds, but by destroying the roots and the stems of valuable plants. They are also particularly destructive in nursery-grounds, where trees are grown in close beds. They conceal themselves in them, and strip the young trees of the bark for some distance above the ground, by which means the tree is as effectually killed as if an American back-woodsman girdled it with his axe.

The royal forests in England have sometimes been attacked by countless thousands of them, the injury done by which to the young trees—to all trees indeed with succulent bark—has been most extensive, and, only that the ravages are directed to a different kind of vegetation, the mischief done puts one more in mind of what is said of the plague of locusts than of any thing else. Singly, these are very feeble creatures; but they show, in a very striking manner, what numbers can accomplish; and this is one among the many practical proofs that we have of the fact, that little foes which make their attacks in large numbers are always the most difficult to deal with.

When the field-voles muster in the full array of their numbers, which they sometimes do both in Britain and on the continent—though in Britain their ravages have hitherto been confined to the southerly parts of the island, and have been most serious in the royal forests—they commit great devastation. On the continent, especially in some parts of Belgium and the north of France, they sweep the lands of the agriculturists with terrible destruction. They first attack the harvest fields, upon which they levy severe contributions, then they betake themselves to the crops that are on the ground, and, burrowing under the surface, remain there till the whole is eaten up. Their next resource is in the woods and copses,

where they gnaw the bark of the trees, which is equally fatal to them, as the communication between the root and the branches is completely broken. The natural enemies of the vales are all on the *qui vive* upon these occasions, just as the natural enemies of the lemmings attend their marches when they descend from the Scandinavian mountains, and pour their destructive numbers over the plains and valleys of Norway and Sweden. The assistance of these, the exertions of the people themselves, the failure of subsistence, and finally the destruction of part of the remainder of those creatures by the cats, ultimately reduce their numbers, and it does not appear that many of them return. In all cases where animals pour in their vast numbers into places where they are not generally so numerous, we may regard their doing so as in some way connected with a wholesome and necessary thinning of their numbers in other places; but the cause of their moving in these multitudes in one season rather than another has not been ascertained.

One year does not appear to be, in all cases, sufficient for effecting the reduction of numbers, which we may suppose is the chief cause of these movements; for in two consecutive years, 1813 and 1814, the New Forest and the Forest of Dean were attacked to a very alarming extent. New plantations had been made in these forests some time before, with a view of replacing the timber that had been cut down, and thus continuing the value of the forest. Such a quantity of plants with succulent bark near the surface of the ground was a rich provision for the mice, which no doubt found the bark of the old oaks and chestnuts rather a dry mess. The mice accordingly mustered to the feast, and began it in their usual style of attacking live plants, that is, by burrowing under the surface and attacking the roots, which in the young trees was of course confined to the bark, though a little further down, where the woody part of the root was softer and sweeter from not being exposed to the air, they ate through that also, though it is fully as probable that the wood was cut through merely from being in the way. They also attacked the bark above the ground, and even scrambled up the trees for it.

The number of trees which they thus destroyed was very great, and the conservators of the forests were thrown into a state of the greatest alarm. Had it been earlier in the history of the country, it is probable that "bell, book, and candle," would have been in requisition, as they were in Canada against the pigeons; but the authorities took human means, that is, they dug numerous pits with overhanging sides, so that once in the vales could not get out, but remained there for the crows to peck at or the keepers to kill. The predatory animals, whether mammalia or birds, which content themselves with "such small deer," as animals weighing about an ounce and a half each, were busy on the ground or in the air; and plying teeth, and bills, and beaks, and claws, with no small zeal and satisfaction. All these means, vigorously as they were applied, were some time in clearing the ground of the little destroyers, and it was much longer of course before the forests recovered from the effects of them.

In many parts of the world there are species bearing some resemblance to the last-mentioned one; and no part of the world appears to abound more in them than the east of Siberia. Of the species there,

there is one called the "*economic campagnet*," which, according to the accounts, is a very interesting creature. They excavate burrows, shaped something like an oven, and about a foot in diameter, to which there are numerous entrances, but they are all too narrow for admitting any predatory animal. Near the chief apartment there are magazines of provision. This is collected in the summer, and consists of various plants and roots, which are dried in the open air. The females, which remain in the burrows attending their broods, are said to perform the chief part of their domestic labours. In some years they collect in the spring for the purpose of migrating in a body, which they do to long distances, considering their diminutive size. In their progress they do not hesitate in crossing streams or even lakes, and many of them perish in the water, or are captured by predatory animals. They generally return from these excursions about the middle of autumn; and the natives are said to mourn their departure, and rejoice at their return, in the superstitious belief that they escape from bad weather and come to good.

REDUVIIDÆ. A family, or more properly a sub-family, of hemipterous insects belonging to the section *Heteroptera geocorisæ*, and distinguished from the other groups separated from the great Linnæan genus *Cimex*, by the very short, curved, and strong proboscis, with the head narrowed behind the eyes into a distinct neck; the antennæ are also very slender at the tips. This sub-family is extremely numerous, and some of the species are amongst the largest and most singular of hemipterous insects. The majority, however, are chiefly exotic. The body is generally long and the legs slender; in many, however, the fore legs are thickened, and the thighs of these legs armed with spines indicating the carnivorous habits of the insects. In many species the thorax is also furnished with great spines, giving the insects a very formidable appearance. They are considerably variegated in their colours, but many exhibit only uniform obscure tints, with occasional metallic reflexions.

The *Reduviidæ* do not emit that disgusting scent which renders the *Cimicidæ* in general so obnoxious; but, as if to make amends for this want, they are enabled to inflict very severe wounds with their short and strong proboscis. They are found upon flowers, trees, and occasionally in houses; their prey consists of other insects which they can overcome. One of the species has received the name of the masked *Reduvius* (*R. personatus*) from the singular economy of its larva, which has the instinct to envelop itself in a covering of dirt and floating dust, in order to conceal itself the more completely from the insects which it feeds upon, and which are chiefly the common bed-bug. It might perhaps be supposed that this coating of dirt was accidental, and had become attached to the insect in its passage through the obscure places of its abode; but such is not the case, for one of these larvæ being enclosed by itself in a paper box and left for the space of a month, was discovered at the end of this period, not only to have shed its skin, but to have coated itself with its old mantle of dirt which it had carefully picked off its old skin. Stationed, therefore, in some obscure corner, the crafty insect waits patiently for the arrival of a victim, upon which it pounces immediately that it comes within its reach, seizing it with its two fore-legs.

The sub-family, from its great extent, has been divided into numerous genera and sub-genera by

Fabricius, Laporte, Burmeister, &c., the chief of which are *Reduvius*, *Zelus*, *Ploiaris*, *Nabis*, *Petalochirus*, *Holoptilus*, &c. The genus *Reduvius* is distinguished by the elongate-oval form of the body, the moderate length of the legs, the anterior tibiae are provided with a cushion at the tip, and the antennae are four-jointed. The type is the *Reduvius personatus*, Linn., which is about two-thirds of an inch long, of a brownish-black colour without spots. It is generally found in houses.

REEVESIA (Lindley). A Chinese plant bearing monadelphous flowers, and belonging to the natural order *Byttneriaceæ*. It thrives in any light rich soil, and may be increased by cuttings.

RENANTHERA (Loureiro) is a splendid genus belonging to the parasitical *Orchidaceæ*. The plant is grown in damp moss in a warm stove, and flowers freely.

RENEALMIA (Dr. Brown). A genus of ornamental perennial herbs, natives of New Holland. The flowers are triandrous, and the genus is arranged among the *Iridææ*. The species, of which there are three already described, are cultivated in the stove, and thrive in turfy-loam and heath-mould.

REPTILE (*Reptilia*). A class of vertebrated animals, and the third in succession in most of the systems, the place being between the birds and fishes. The name "reptile," is derived from the Greek word signifying to crawl or creep; and thus it is not very descriptive of the whole of the order, neither does it express a kind of motion which is peculiar to those animals which the order includes. Among vertebrated animals, indeed, there are not any that can be called creeping animals, except the creeping reptiles; but, when we come to the invertebrated animals, we find very many that crawl or creep. Among reptiles, too, there is to be found every kind of motion which is found among any of the other three orders of vertebrated animals; but it is not performed by means of organs exactly similar, or in exactly the same style. Thus, for instance, many reptiles walk, run, or leap, and some of them with great agility; but their limbs, though they consist of nearly the same number of bones, are not articulated like those of the mammalia. The limbs of a reptile have always something the air of supplemental bones stuck upon the body of it, and not parts of the whole as one harmonious organisation. Some reptiles are capable of performing a sort of flight; but they do it by means of membranes, and not of any organs resembling wings properly so called. Those that swim, and many of them are excellent swimmers, do not perform that motion by any thing resembling fins, but by the flexure of the body or the action of the limbs. Even the creeping or crawling of reptiles is different from that of the invertebrated animals, chiefly *Mollusca* and *Annellidææ*, which perform the same description of motion. In both of these, there is an alternate "holding on," by means either of different portions of one sucker-like foot, or of two such organs, at different parts of the animal; and the real motion is performed by the alternate lengthening and shortening of the body. The possession of a vertebral column prevents any lengthening or shortening of the body in reptiles, and, therefore, those which have no feet, perform these motions by means of flexures of the body, though in many of the species this motion is so rapid that they seem to glide along. In order to produce these, there must be a concentration of muscles on

the spine. This, however, though it holds in many of the genera, by no means holds in all the class; for there are three of the four orders into which it is divided, which have but little motion of the dorsal part of the spine, and some which have none at all. In the class of reptiles, therefore, we are unable to lay hold of any general character of the organisation or the mechanical action, which will carry us through the great majority, and thus enable us to see their place and use in the world, before we come to divide and distract our attention with the details.

There are swimming mammalia, and there are mammalia which can perform a sort of flight; but, notwithstanding this, any one who takes a general view of the mammalia as a class, can be at no loss to say that they are the inhabitants of the land or solid parts of the earth's surface. If the examination is continued until it becomes more minute and runs into the differences which appear among the order of the groups and sections, it only requires a corresponding knowledge of the different parts of the land itself, to say where each of these shall find its appropriate habitation; and the few mammalia, in comparison with the whole number, that are inhabitants of the water, are just as easily pointed out, as it is to decide when we see an ape and an antelope, "That climbs a tree by grasping with the hands, and this bounds along over firm surface of the earth."

There are also some birds which have not only got no flying feathers, but which have got the bones of the wings merely rudimental and enclosed within the skin of the body; and there are some others which have the wings more like swimming flaps than like instruments for moving through the air; yet, when we take a general view of the class, we have not the least doubt or hesitation in coming to the conclusion that there are creatures which, upon the whole, are fashioned for making their way through the atmosphere. Even in the case of the wingless and the flap-winged ones, we come nearly to the same conclusion; and upon examining them we feel that, if a little more were added to them, they would quit the earth or the waters and soar aloft. If we go into the details here also, we have no difficulty in inferring the locality from the structure, and pronouncing one to be of slow flight, and another of rapid—that one is a tree bird, another an air bird, a third a ground bird, and a fourth a water bird. It must be admitted that from mere examination of the structure of birds, we cannot so well tie them down to geographical localities, as we can so tie down the mammalia. This we might expect from the nature of the element in which birds move. The air circulates freely round the whole of our planet; and the very same portion of nitrogen which is given out in breathing by a man at London, may, after unking again with the requisite quantity of oxygen, be breathed by a man at the antipodes, after the lapse of no very great number of months, or even of days. Therefore, it is perfectly natural to conclude, that the bird which can ride in the air as in a chariot, should partake something in the discursive power of that chariot; and that the bird which is under the line at one season of the year, should be near the margin of the polar ice at another. But this does not prevent us from easily arriving at the general place which birds occupy in the system of nature, or the particular place of any one genus, family, or other division or sub-division, which has in its different members so many characters in com-

mon, as that we can say they must all follow the same mode of life.

Fishes are less under the control of our observation than either mammalia or birds; but there is this advantage in them, that, when they get out of the reach of our observation, we know where they are, and that is not an unimportant point in our knowledge of them, though it may appear a vague one. Fishes leave their own appropriate element less than either mammalia or birds, though there are a few that can (not fly, but) leap a little way through the air, and others that can crawl a little on the surface of the earth. Both of these are, however, in the metaphorical as well as the literal sense of the words, "fishes out of the water;" and thus they form not the slightest hindrance to our conclusion as to the place which fishes hold in the system of nature. As in the other cases too, if we attend to the differences of structure, we have not much difficulty in coming to an accurate conclusion as to the place and the general style of action in any particular fish. A very cursory look will inform us whether the fish lingers near the shore or drives about discursively over the wide seas. Nor is it more difficult to determine the general depth at which the fish inhabits the water, to pronounce that it is a surface fish, or fish of the midway depth, or one of the bottom.

In each and all of these three classes of animals, therefore, we have something to begin with, which is easily traced, clear and definite, and of ready application at every step of our progress. But when we attempt the study of the reptiles we have no such help. We can of course tell the shape, and the number, form, and arrangement of the several parts; that is to say, if we get hold of the specimen in a condition sufficiently perfect; and there are some few cases in which we can tell whether the land or the water is the habitual residence of the creature. But there are other cases, and they appear to form the majority, in which we cannot decide even this very simple and general question—a question so simple and so general, that, though we could answer it, the answer would be of very little value to us.

Let the reptile in question be an ophidium, and let the question be whether it is a land one or a water one; and without a knowledge of those very details in which the general principle ought to assist us, we can come to no conclusion. Even in those with which we are most familiar, there are puzzles and perplexities of the very same kind. Let any one who has not attended to the habits of the creatures look at a common frog, as it hops lightly along the meadow, and at a common toad, as it drags its apparently useless lumber of legs after it on a dark evening in the middle of summer; and, after he has examined their appearances and their motions, let him say which is the more aquatic of the two, and the chances are, that if he is in the proper condition for needing the general principle, that is, if he knows nothing about the facts of the particular case, then the chance, nay, almost the certainty, is that his decision will be wrong.

Owing to this total want of a general character in keeping with the rest of nature, by the help of which we could arrive at some knowledge of the locality, latitude, and use, we are, as it were, thrown out of the system when we attempt to take a general view of the class of reptiles in reference to the system and working of the rest of nature. They are vertebrated

animals, and yet they do not appear to belong to the same combination as the other vertebrata. We can at once point out the general element or locality of a mammiferous animal, a bird, or a fish, but where, upon general principles, is the proper element or locality of a reptile? From inspection of it, we find that, flying excepted, we might with equal propriety point anywhere, and that which is equally at home anywhere may be said to be really at home nowhere.

This negative state, so to name it, in which we are placed with regard to the reptiles, as having light thrown on their characters and uses, from the economy of the rest of nature upon our globe, leaves us absolutely without anything like general or scientific principles in the natural history of them—absolutely without a rational natural history, we may say; for all the knowledge that we have is mere details, as these have been observed in individual instances; and we may add that there are, in the various collections, more specimens of reptiles, of the habits, and, in many instances the mere localities, of which nothing is known, than there are of all the other vertebrated animals taken together.

If we abandon the mechanical structure and the mechanical action, and take to the physiology, we do not materially better our condition as to general knowledge, for there seems to be the very same kind of anomaly here as in the mere structure. Among the whole of the other three vertebrated classes, for instance, there is a production of a certain structure, at the birth or the coming out of the egg, though different parts of this are developed and brought to maturity at different ages of the animal. But if, by accident or design, any member is lopped off, the mutilation continues, and though there may be compensation in other parts of the system, there is never any reproduction of the severed member. But it is not so in the reptiles; for in many of them, a limb, or part of a limb, will sprout again and grow, and come to be useful after it has been completely taken away. In this there is a complete departure from the other vertebrata, and an assimilation to some of the animals that have no skeletons, and nothing that can be called a centre of organisation—to the crustacea for instance, and also to some of those creatures which appear to hold the lowest rank in the scale of animal life, and which may be cut in pieces without being killed, or dried like tinder, without being so far dead as that they cannot be again resuscitated by the application of the requisite supply of moisture and of heat.

Indeed, the reptiles generally are wonderfully at the mercy of the laws of the inanimate part of creation; and though some of them are capable of very powerful momentary action, they are so only when they have due assistance from physical causes external of themselves. The great crushing serpents, which can break the bones of very large animals in their folds—the pythons of the south-east of Asia—and the boas of tropical America—are perfectly helpless if you expose them to the cold of even a mild winter day with us in the open air, or even in a room where there is no fire. When the temperature is reduced below a certain degree, they sink so that they cannot recover, and then of course they die; but, down to a certain degree, the measure of which is a matter of experiment, they may be kept in a dormant state for a great length of time; their

functions, while in that state, may be so totally suspended, that there shall not be the slightest wear or waste of the system, and yet the application of heat shall restore them to the full measure of activity which they enjoy under any circumstances. The enclosing of a common toad in the hole of a tree, by the growth of new wood over the aperture, is a case of which there have been many instances.

In this way the more characteristic of the reptiles afford a remarkable proof of a very curious doctrine—a doctrine which, at first sight, one would be tempted to look upon as a paradox, and yet which, when we come to analyse it, appears to be perfectly consistent with the general law of nature. The principle is this: the less of the activity of life there is in any creature, taken in the average healthy state of that creature, the more difficult is that life to be destroyed. A tortoise has been known not only to live, but to move about, for nearly three weeks after the brain had been totally removed. A salamander, which is a reptile in which the action of life is still more feeble, has been known to live for several months; and the hearts of some serpents have preserved their vitality for nearly two days and two nights after having been taken out of the body.

In fact, it does not appear that any of the functions of reptiles are so purely animal functions as those of the other vertebrata, or even some of the invertebrated ones, in which the action of life is very vigorous, and therefore very easily destroyed. Digestion is one of the most important functions of animals; and in the other vertebrata, the process of digestion appears to sweeten the food in many cases, where it cannot be supposed to be very sweet before it is taken into the stomach. In them the gastric fluid, though a powerful solvent, is anything but a putrifying agent; on the contrary, it is an antiseptic. To enquire into the chemical causes of this, and attempt to ascertain how much of it is owing to the peculiar alkali in this stomachic agent, would be foreign to our purpose. It is certain, however, that not a little depends on this, for there is nothing which deranges the whole system of an animal to a greater extent than an excess of acid in the stomach, which acid neutralises the alkaline property of the gastric juice, which thereby becomes unfit for the performing of its function, and indigestion and derangement of the whole system are the necessary consequences; and, when this derangement is great, the contents of the stomach become offensive, and the food is converted into a poison. Those who have to earn their bread by mechanical labour, in the open air, are very rarely affected in this way; and we may thence infer that, in so far as the mere body is concerned, this is the natural state. With man, as a rational and immortal being, the body, though an important consideration, is not the only one. But in the case of other animals it is quite different. In a state of nature they all perform the labour of finding their food in the open air; and therefore, in the three typical classes, and especially in the mammalia and birds, the contents of that stomach in which the food is turned into chyme are always sweet. So much is this the case, that, in some instances—as in woodcocks and other gut birds—the “trail,” that is, the stomach and its contents, is esteemed as the most savoury and delicious morsel of the whole. Very many of the predatory animals, also, endeavour to reach, as soon as

possible, the stomach of their prey. All the facts, indeed, tend to show that, in the healthy digestion of mammalia or birds, and even of fishes, there is a correcting of putridity, and not a producing of it.

But, when we come to the class of reptiles, we find the state of things very different; for their digestion appears to be a putrefaction, and it is possessed by the gullet, and probably even by the skin of the interior of the mouth. What connection there may be between this tendency which the digestive fluid in reptiles has to putrify the food, and the actual poison which some of them secrete, as a means of killing their prey, of defence against their enemies, or, as it is in the poison-pores of some of the *Sauria*, for purposes not very well known, it is not easy to say; but we know enough to make us infer that there is some connexion between reptiles and putridity. This is not of course equally conspicuous in all, for the reptiles are a diversified class; and though we cannot infer, *a priori*, from their structures, in what latitudes or in what places any particular one ought to dwell to be in greatest accordance with that harmony which runs so conspicuously through nature, yet we find that their great head-quarters agree with the physiological distinction between them and the other vertebrata in the nature of their digestion; and this, though not a great deal, is some beginning to their history as a portion of nature.

It is a law in the economy of the world, to which we believe there is no exception, that where there is most life there is also most death; and where composition and growth operate with the greatest vigour, there decomposition and corruption, which is but another name for one form or stage of decomposition, are always most vigorously at work. Countries near the tropics, which are shaded by woods, supplied with waters, or otherwise so provided with moisture as that they do not become parched during the rainless season, are of course those in which life and death are most powerfully and constantly at work. We have again and again had occasion to point to the islands south-eastward of Asia, and the countries on the north-east shore of South America, as those which possess this character in the highest degree. Now, it is there that we find the grand muster of the reptiles, in variety of species, in numbers, and in power. Such as inhabit the waters are not of course much affected by the fertility or barrenness of the land. They depend more on the productiveness of the water, and the action of the sun as affecting its temperature, and promoting the hatching of their eggs. It is probable, however, that there is some connexion between the fertility of the land and that of the sea, though the knowledge of this has not yet been reduced to anything like part of a system.

The more powerful of the reptiles, whether those which we call aquatic or not, which are to be met with in those places of continual growth, are in other places less abundant, as they less resemble these in their physical characters. The banks of a large river, the woods near its confluence with the sea, or marshy lands, if in warm latitudes, are all favourite places for the abodes of reptiles. In such places, crocodiles, alligators, and turtles, are found in the waters, vast numbers of toads in the marshes, lizards in the drier places, now in the sun now in the shade; and serpents, coiled up under the bushes, basking in the sun, lying in wait on the trees, or swimming from place to place, are found in countless numbers; and the

M M

size, the strength, and the venom—whatever the creature has to depend upon for its strength and protection—is always in proportion to the general action of nature in the place which it inhabits.

Those which have their habitations in the sea, also, all point to the tropical countries as their headquarters; and they, as well as the land ones, so far follow the climatal distinction of the two hemispheres, as that they go into higher latitudes in the southern hemisphere than in the northern. As we get into the high latitudes, the numbers, the size, and the power of reptiles, whether of the land, the fresh waters, or the sea, rapidly decrease, till, in the extreme regions near the poles, there are few or none. The northern hemisphere has been examined with the greatest care; and it affords the best field for examination, as there is, in one longitude or another, continuous land all the way from the equator to the polar ice.

From the examination of it, we find, that the sea-reptiles are the first to fail, while the fresh-water ones are among the last. We might be prepared to expect this, from the fact, that very few animals can hybernate in the sea, and none, perhaps, in the deep water. It has been alleged, that some of the surface fishes, as, for instance, the mackerel, sink down into the deep water, and remain dormant there at certain seasons of the year; but the point would be very difficult to establish, and we are not aware of the existence of any sea reptile which hybernates. Even in the warmer seas of Europe, reptiles are few; and in the British seas there do not appear to be any residents, and very few stragglers. In the fresh waters there are none but batrachians; and the land ones are not many, and in the northern parts they are exceedingly rare.

On the continent it is different; for fresh water tortoises are found nearly up to the southern shores of the Baltic, and there are poisonous serpents in Sweden and Norway. This also is what we might be prepared to expect; for, as these are hybernating animals, they do not depend on the average temperature of the year, but on the heat of the summer, or season of their activity; and, though the average temperature is lower in the countries mentioned than it is in Britain, yet the excess of cold is thrown upon the winter, and the summer is considerably warmer. We have a very good illustration of this in many parts of Scotland, where there are snakes in the hills, while not one is ever seen upon the plains between these hills and the sea, though the average of the year is much milder there. The summer, however, is not nearly so warm, at least during the day, as these plains are cooled by the sea breezes, while the heat among the hills is increased by reflection, till, in some places, it is as high as summer tropical ones, and it lasts for a longer portion of the day, from the sun being, for several weeks in the middle of the summer, four or five hours longer above the horizon.

From the way in which they are distributed, we can thus see how the present race of reptiles is affected by the physical character of the climate; and as that confines by far the greater number of them, and all the most powerful ones, to the warm latitudes, we may naturally conclude that these are the only places where they are now required in the economy of wild nature.

In former times it must have been very different, for we have very numerous remains of fossil reptiles

in the northern parts of the world, and in England in particular; which proves that, at some former period, they must have been a conspicuous, and therefore an essential part, in the system of animal economy. The fossil reptiles which have been found in various formations, more or less consolidated into stone, are chiefly, if not wholly, either chelonian or saurian. The *Chelonian* are of the forms now inhabiting the waters, some of them apparently of the fresh waters, but the greater part of the sea. Remains of crocodiles are not rare, some of them bearing a resemblance to the existing species, and some not; but of many of the other fossil sauria there are no existing types, neither are there any living members of the order which rival some of them in size.

But, though the reptiles which have the nearest resemblance to these extinct species are now found only in more tropical climates, that proves nothing with regard to the climate of England in former times, nor, which would be more to our present purpose, does it throw any light upon the nature of reptiles. We know, from the almost perfect remains found in the north of Siberia, that there must at one time have been elephants—not an occasional straggler, but in such numbers that the teeth formed a considerable article of trade—so formed as to endure the very extreme of cold, and with bristly hairs interspersed with their fur, capable of shaking off a fall of snow, however heavy. The remains of the other *Pachydermata* which are met with indicate a marshy state of the country; and, as these great fossil reptiles, which, from their situations in the earth, are obviously of much more early date than the extinct mammalia, are all aquatic, we may conclude that the northern parts of the world have been in a progress towards dryness, which, from what we at present observe, is one means of unfitting them for the abodes of reptiles.

This gives us another physiological character of the class, which, though of rather a shadowy nature, is yet of some use in a case where we can found so little upon organisation, and also lets us see the reason of the difficulty we labour under in endeavouring to get a general understanding of the nature of this perplexing class of animals. The reptiles are not peculiarly land animals (including both mammalia and birds under that denomination), neither are they aquatic animals; but they are animals of the boundary between the two, and thus have no breadth of native locality in which we can link them with vegetation, or otherwise bring them within the general laws of the rest of the system as we now observe it. With only one or two exceptions, they all, when in the native state, breathe the free air like land animals, but they do it slowly and imperfectly; and many of them even suspend their animation for a great length of time, or rather, it becomes suspended of its own accord, when the stimulus of heat is sufficiently lowered.

In the production of their young, they vary from a resemblance to the birds to a resemblance to the fishes; and in the last part of the series they resemble both kinds of fishes, in some being oviparous and others ovoviviparous. The very texture of their bodies, bones, membranes, fibres, and all, have something of this intermediate character. The bones contain less phosphate of lime than those of the mammalia and birds, but more than those of the fishes, and gelatine predominates in all the soft tissues and structures of their bodies.

. This fact of being intermediate in their motions and also in their principal localities, very naturally leads to the conclusion, that they are also intermediate in their history; that, for example, in respect of any particular place on the surface of the earth, they stand intermediate between the times when the principal character of that place is water, and when it is land. We are generally disposed to regard the ancient account of the *Ultima Thulé*, which was placed in the extreme north, as a mere fable; but really *nec tellus nec mare* is the very kind of country which would suit the great saurian reptiles which are found in the earth; and we may add, that, if the parts with which the bones of some of these creatures were covered, bore any proportion in singularity of structure to the bones themselves, a tolerable foundation is furnished for many of the monsters of antiquity, without much necessity for having recourse to fable. Thus, if the history were complete, which unfortunately it is not, a proper knowledge of the reptiles would throw more light upon the ancient history of the globe than could be obtained from any other animals; because the others indicate a fixed state of things with the surface, either land or water, and the reptiles indicate the transition from the one of these to the other. As they exist, they belong to places of great stimulus and excitement; and we may presume that when they were more general, that state of things was more general also.

The next part of the subject will be the consideration of the particular kind of structure which the reptiles bring to the performance of their duty in nature; or, rather, the kind of structure which enables them, and indeed compels them, to be so obedient to the action of physical causes. In this we shall glance very briefly at the different systems and structures, with the way in which they act or are acted upon; and having done this, we shall give a mere outline of the classification.

In this first part the skeleton is always the portion to begin with. We have remarked that in general the bones contain less salt of lime than those of land animals, but there are differences in this respect. The bones of the small ones are of the same structure throughout, without any cells for containing marrow; but in the larger *Sauria* there are such cells, though comparatively few in number.

The cranium properly so called, or the bony protection of the brain, is very small in all reptiles, which forbids our supposing that the energy is much concentrated in that organ, or that the senses of which the organs obtain their nerves immediately from the brain can be very acute. The vast production of the jaws in some of the species makes the head appear large. There is very often a considerable difference between the young animal and the adult in the form of the head; and one who was not aware of this would be apt to set them down as different species. This is the case, to a very considerable extent, with the crocodiles. When young, their foreheads are rounded in the contour, their muzzles are short and blunt, and the eyes are placed about the middle of the length of the head; but as they increase in size, the roundness of the forehead disappears, the jaws lengthen, the head appears very flat, and the eyes have a backward situation, so that they are three-fourths of the total length of the head from the point of the muzzle. In them, and also in the tortoises, the skull is a sort of flattened cone, with the brain in the posterior or basal

part; and in others of the order it is a prism with the edges rounded; but in all the cavity for the brain is simple, and of nearly the same width throughout its length.

The vertebral column varies much in the reptiles, and in some of them there is hardly any distinction of articulated parts; while in others there are some of the most varied and perfect motions in the whole mechanical structure of animals. In the tortoises, crocodiles, and some others that have distinct necks, the number of vertebræ is seven, the same as in the mammalia. The vertebræ of the back vary in different tortoises, being not more than eight in some, and as many as eleven in others; and there are generally three vertebræ in the tail. Those of the tail have considerable motion; and in the neck they have more extent and variety than is to be met with in so short an organ in any other animal; and, besides those that move the joints of the neck, there are other long ones attached to the frame-work farther back, by means of which the creature may be drawn into the horny shell. The vertebræ of the back have not the slightest motion, but are soldered into one piece with the bones which answer to the ribs, and the shield or dorsal portion of the shell. In the crocodiles there are twelve vertebræ in the back, five in the loins, two answering to the sacrum, and thirty-four in the tail; but, except in the tail, the articulations have not much freedom of motion. The frogs have about eight or ten vertebræ, according to the species; but as these form a simple column without any ribs attached, they cannot be distinguished like those of an animal having ribs. The spinal muscles are concentrated upon the neck in the tortoises, upon the tail in most of the *Sauria*, and in the frogs they are few.

The thorax, for it cannot be called the chest in all the species, varies a great deal. In the tortoises the ribs are confined in the shield on the back, and the sternum is blended in the breast-plate. The *Sauria* have the anterior part of the sternum bony to admit of attachment to the clavicles, but it passes into cartilage backwards, and ultimately divides into eight cylindrical cartilages, which brace and strengthen the belly like ropes. The ribs are twelve, but the two nearest adjoining the front, and the two in the rear, are not attached to the sternum. Some of the lizards have the greater part of the ribs joined by cartilaginous arches; the salamanders have them only rudimentary, and the frogs, though they have no ribs, have a sternum. Thus, from the crocodiles to the frogs, there is a gradual lessening of the connexion between the dorsal part of the spine and the sternum. The muscles which give motion to the same parts of the body are not very powerful; and in the tortoises and frogs which have no motion of ribs, the abdominal muscles are attached to the breast-plate and the sternum. This enables the frogs to inflate the body by swelling out the skin of the sides.

The cavity in which the head of the humerus, or first bone of the anterior extremity acts is, in the majority of reptiles, with feet formed in two bones—the blade-bone, and what is usually called the clavicle. It is doubtful, however, whether this clavicle, which is a short flat bone extending from the sternum to the shoulder-joint, is not a *coracoid* bone like that which supports the wing-joint of birds from the sternum; and this is rendered the more probable by the turtles having a furcal bone somewhat resembling

that of birds, and being of course the true clavicle. It should seem, therefore, that footed reptiles which have not this furcal bone are really without clavicles. This agrees with the style of their action. We have shown, see art. MAMMALIA, that the possession of a clavicle, though it is favourable to the cross motion of the anterior extremities, is always a drag upon their efficiency in walking, though not necessarily in leaping, as the spring is then taken from the hind legs. Now, while some of the other *Sauria* run with no inconsiderable degree of celerity, the tortoise with its clavicles forming a distinct furcal bone, is one of the slowest of walkers.

This coincidence between the shoulder of a reptile and that of a bird, in the fact of both having coracoid bones, is a very curious matter; the curiosity of it is still further increased when we consider that the tortoises have the shoulder articulated very much like that of a bird, by the support of all the three bones; and these coincidences become still more interesting when we find that they are greatest in those cases where the mode of production in the reptile resembles most nearly that of a bird.

In the shoulder of the turtle, the bone which answers to the scapula or blade-bone, is united by cartilage to the first rudiment of a rib, from which it extends to the shoulder joint. The coracoid extends from the breast-plate to the same; and the third, or furcal bone, extends backwards below the viscera as far back as the abdomen. These bones form an opening for the windpipe and gullet in the same way as in birds; and they may be thus compared to the shoulder of a bird, inside the principal supports of the body, and not outside as the bird has them.

The anterior extremities consist of an arm, a forearm, and a hand or paw, as in the mammalia. The arm consists of only one bone, the humerus, as in these. The fore-arm consists of two bones, except in the frogs and toads; and the hand, and also the plane of the principal articulations of the whole number, are varied to suit the purposes which they are intended to serve. In the aquatic tortoises, or turtles, the joints are formed for the motions required in swimming only; and the paw, though internally composed of many bones, is entire externally, so as to be a swimming paw or paddle. In the *Sauria* the hands have a number of divided toes varying from five to one only, variously armed with claws, and capable of most of the motions to which feet with divided toes are applicable; but, in their general appearance, they may be said to be intermediate between the feet of mammalia and those of birds. The feet which they most resemble are those of the marsupial mammalia.

The pelvis, which is the base of insertion for the hind legs, is of considerable size; and the bones of it, contrary to what exists in the mammalia, are moveable on the spinal column, instead of being soldered to it with little or no power of motion. It is this which makes the hind legs appear to be only appendages, and the tail the real continuation of the body; and this appears the more from the thickness of the basal part of the tail in many of the species. But even in the frogs, which have no tails, the hind legs still have the appearance of appendages; and in the best-limbed of the race, there is always a suggestion of the footless reptile. The femur or thigh-bone is curved so as to bend backwards at its upper part and forward at its under, something like the letter S.

There are two fore bones in the leg in most genera; but in the frogs they are soldered together. The bones of the hind feet are like those of the fore, and, like those, adapted to the peculiar kind of motion which the habit of each requires it to perform. The muscles on the legs of frogs form a sort of calf.

In the positions of rest and style of motion, there are great diversities. Water-turtles stand on the breast-plate as much as on the legs; land tortoises stand on the legs; frogs and toads sit with the axis of the body oblique, and supported anteriorly on the fore legs; and those saurians which approach the nearest to the serpents have the power of coiling themselves up when they are in a state of repose. Turtles shuffle along, but do not walk; tortoises walk slowly; the saurians are walkers, leapers, or climbers, according to the nature of their haunts and their mode of obtaining their food; and none but the dragons can fly, and their apparent organs of flight are mere parachutes, which protract their fall, and not wings that can gain new motion from the air as a fulcrum or starting-point of resistance.

In these few remarks, we have made no allusion to the structure and motions of the serpents or ophidian reptiles, because they have little in common with animals having limbs, and therefore it will conduce to the clearness of our brief view of the class if we take them by themselves. We shall therefore notice the remaining points relative to the others.

Considered with regard to sensation reptiles have even less brain in proportion than they have cranium, and the little they have is very imperfectly developed. They cannot therefore have much of what may be called internal excitement, that is, of originating action with very little impulse from without. But, by wanting this, they are left the more exposed to the influence of external causes. This is what keeps them more to certain latitudes and localities than any other animals; and in respect of the weather in changeable climates, they are excellent weather-gauges in all places where they will live exposed to the weather.

In respect of quantity of brain there are, however, great differences: the brain of a turtle is not supposed to be above a six thousandth part of the whole, while that of a frog is more than a two hundredth part. The frog should, therefore, be an animal of much greater resource, and it may be on this account that it lives in a greater variety of climates.

Though the muscles of reptiles have great irritability, and this continues a long time after death, it does not appear that they have much of what is properly called sensibility; and that their motions and the effects of external impressions on them are much less productive of pleasure or pain than those of mammalia and birds. They have some of the organs of local sense well developed, and others very imperfect.

Of their touch, or feeling, or general muscular sense, it is difficult to judge, because it cannot be separated from the irritation produced by the mere contractibility of the muscles. Sight appears to be their most perfect local sense. The eyes in most are well-formed and ready in use. The turtles, some of the *Sauria*, and the frogs, have the eyes supported by bony plates on the anterior part of the sclerotic coat, and this is seldom found in eyes which are not intended for quick and steady vision. The iris of the eye varies in colour, though less than in most of the

other classes, and the prevailing colour is yellow. There is very considerable variety in the form of the pupil. In the crocodiles it closes on a vertical line as in the common cat; in the frogs, and in the geckos among *Sauria*, it is four-cornered, and in the common lizards, the chameleon, and the tortoises, it is round. As in the fishes, the crystalline lens in the whole, or, at least in the greater part, is spherical, by which the animals can see under water, whether their general habit is aquatic or not. Those which have two eyelids closing toward each other, have a third or ventilating one as in birds, and some, as the crocodiles, have a bone in the upper eyelid. In the lizards there are not separate eyelids, but an outer membrane surrounding the whole length, which closes toward the centre by means of a sphincter muscle, much in the same way as the iris closes and contracts the pupil. Thus the eyes of reptiles partake of the structure of those of birds and those of fishes jointly; they have very great power over the apparatus of their eyes; and a few, as, for instance, the chameleon, can look two ways at the same time, but whether it can fully see a separate object with each eye is another matter. Sir Walter Scott was perhaps not aware that he was making a chameleon of Andrew Fair-service, in the novel of *Rob Roy*, when he represented him as sitting on the sabbath, with one eye intent on the Bible and the other on the bee-hives, equally zealous for the interests of the next world and the present.

Though many reptiles live in dark and gloomy places, and rarely, if at all, come abroad in the daylight, yet it does not appear that the eyes are affected by it, because they are well fortified, and there are some which have to bask and sport in the most intense radiance of the tropical sun. In this, as in all other cases, the external action upon them appears to address itself more to their irritability than to their sensation.

It is very doubtful whether any of their other senses are so acute as the sense of sight. As to hearing, there are few or none of them that have external ears except the crocodiles. That alone would not, however, be sufficient to establish the fact of their being dull hearers; for there is no reason why the external integument of an animal should not be an organ of the sense of hearing, as well as the tympanum of an ordinary ear is. But, in general, the internal parts of the ear, although never entirely wanting, are less perfect than in those animals which are known to have the sense of hearing the most perfect. In the turtles the tympanum is under the skin, composed of cartilage, and with but a single bone. The saurian reptiles have nearly the same kind of tympanum; but the bones are more numerous, and there are some additional parts bearing a resemblance to what are supposed to be the organs of hearing in fishes. The frogs and other members of the order to which they belong have the membrane of the tympanum large and on the same plane as the integuments; and if abundance of noise in any animals be a sign of hearing, then the frogs can have no lack of that sense; but the music of their voice is assuredly no argument in favour of their having an ear for music.

The organs of smelling are also not of the most perfect kind; and from the places in which many of the species live, they would at all events require not to have very delicate senses in this way. These

organs chiefly open at the termination of the snout, and extend thence to the mouth by cavities lined with membrane, not unlike the olfactory or pituitary membrane in the mammalia. The external openings are furnished with muscles, by means of which they can be contracted or dilated, and the power of motion in the external nostril is rather an argument in favour of some acuteness of smelling. In some too there are bony plates supporting duplicates of the membranes, and thus increasing the quantity of its surface. In all of them however the cavities, and consequently the extent of membranous surface, are small in comparison with those of the mammalia. Yet it is probable that not a few of them depend a good deal upon this sense in the finding of their prey. Many prey during the night, and, climbing trees, eat the eggs and the callow young of the birds which nestle there; and, as many of the birds nestle in holes of which the openings are small, it is difficult to understand how they could be found out, unless by the sense of smelling.

The degree in which they possess the sense of tasting cannot be very great. The tongue varies much in form. In some, as the crocodiles and the tortoises, it is short and fleshy, and furrowed or covered with small papillæ on the upper surface; but it is fastened to the lower jaw both at the sides and the end, and thus incapable of much motion. In some it is very mobile, in others prehensile to a considerable length out of the mouth; the termination is sometimes an elastic cartilaginous fork, and at other times it is toothed. It is, in many instances, of use in seizing the prey; but the extent to which it is an organ of taste is not known. The probability is, however, that there is very little taste in any reptile. Their teeth are in no case instruments of mastication, but of prehension, or they assist in working the prey into the mouth, which prey being in the majority of cases swallowed entire, does not admit of being much enjoyed in the way of tasting.

The system of nutrition is that which next claims our attention. With almost the solitary instance of the green turtle and land tortoise, so much prized by epicures, the reptiles feed upon animal substances, upon animal carrion in a few cases; but in general they kill their own prey, and in many cases swallow it alive.

The nutritive system, considered with reference to the organisation, consists of three parts, prehension, swallowing, and assimilating, including under the latter the various steps of digestion. The mouth is the grand instrument of prehension, and it varies much in the armature which fits it for this purpose; but it cannot be considered as performing any other office than that of simply taking the food and holding it until it is swallowed.

The tortoises have the mouth the most simple. It is without teeth in any of the order. There are jaw-bones, with intermaxillaries in the upper jaw; and these jaws are armed with a horny covering which invests the bone like a hoof, and varies a little in hardness. In some species too the sides of it are nearly even, but in others they are waved so as to have some slight resemblance to teeth. The anterior part of it is sometimes drawn out into the form of something resembling a bill. The upper jaw of the turtle has no motion upon the skull, but offers a firm resistance for the lower one to close against. The lower jaw is articulated on the skull, and has little or

no motion, except opening and shutting; but in some of the species it shuts with great force, and when once shut it is difficult to be opened against the will of the animal. The horny mandibles of the turtles can readily divide substances, some of them even a cable: and therefore the strength of their muscles is thrown upon those that close the jaws, rather than on those that aid in swallowing.

The mouth shuts in the same way in the *Sauria*, but they are furnished with teeth, and the jaws are in general very much produced; and the motions of them contribute both to prehension and swallowing. Among the most formidable mouths in this order are those of the crocodiles, though some of the extinct species show by the remains that they had been animals of most comprehensive gape.

The old belief was, that the jaws of a crocodile shut in the opposite way to those of any other animal, by the upper jaw moving and the lower one being fixed; but the fact is, that both jaws move, and thus the mouth is opened or shut with very great celerity. The lower jaw is not articulated on the skull as in the turtles, but on the upper jaw. That jaw is very long, and the skull, which is small, is lodged in the fork formed by the two maxillaries, and carried with them in any motion they may have. It is this enlargement of the maxillaries, by the way, which changes the round head of the young crocodile to the flat head of the old one. This long upper jaw can be elevated or depressed by the motion of the whole vertebræ of the neck, and partially by those of the back also, so that the face of it in which the teeth are may be brought to the perpendicular, or even to incline a little backwards. This has the same appearance, and also produces the same effect, as if the upper jaw had a motion on the skull, and it offers a firm resistance to the lower jaw in closing the mouth, which could not be obtained if the upper jaw had a motion on the skull. Indeed if both jaws so moved, the bite of the animal would be feeble and unsteady. The lower jaw is articulated on the upper one, and opens from it and shuts against it in the same manner as if the upper did not change its position. The advantage which the animal draws from this is the ability of biting upwards, or with the line of the closed mouth at right angles to the surface of the water. Its prey is often on the surface, and thus it can lie in wait with the snout above the surface, and thus make a more certain capture. Its teeth are formidable, but they are not capable of dividing a substance, and therefore, as the mouth does not dilate beyond the measure of the jaws, the animals are said to bury their larger prey until it becomes tender enough to shake to pieces.

The other saurian reptiles have much less power in the bite than the crocodile tribe, but some of them have teeth in the palate which aid in the operation of swallowing. The tongue of the chameleon is one of the most curious prehensile instruments in the whole class of reptiles. It is nearly cylindrical, and about the thickness of a goose-quill, rather thicker at the point than in the basal part. When in a state of repose, it is drawn into a sheath in the posterior part of the mouth; but when used, it is projected with great celerity to the length of five or six inches, and at the same time the distal portion becomes covered with a viscid secretion. It seldom fails in killing and attaching the insects at which it is directed, and then it is withdrawn, and by its contraction assists in swallowing the prey.

* The entrance to the gullet is simple in reptiles, and the gullet itself is wider in proportion than it is in animals which can masticate, or even bruise the food with the mouth. In many it is beset with papillæ, having their points directed downwards, and in most there are longitudinal folds, which by spreading to receive the food, and closing after it, facilitate its passage into the stomach.

The stomach in reptiles varies very considerably in shape, and sometimes it is doubled back in a curve, but is in all cases a simple stomach; and though the intestinal canal varies in form in the several members of the order, it may in all cases be said to be without cæcal appendages. The progress of digestion, like that of most of the functions of these animals, appears to be but slow; and the action of the gastric juice is chiefly confined to the stomach, the solvent power of the gullet, and whole internal membrane from the mouth down to the stomach in which the first stage of assimilation is completed, being confined to the ophidian reptiles, the notice of which we shall take by itself for the reason already stated.

But though the process of digestion appears to go but slowly on in the generality of reptiles, there are many of them which are exceedingly voracious when they do eat. In most cases the food consists of worms, insects, molluscs, and other small animals, though some take larger prey. The turtles live on some species of sea-weed, which grow only in the warmer latitudes; and is, from their feeding upon it, called turtle-weed, or turtle-grass; and the land tortoises eat the succulent leaves of plants, being particularly fond of lettuce, though their meals of it are taken at long intervals. Some of the species gorge themselves to the throat, and part of the prey which they have seized, but have not room to swallow, occasionally escapes unhurt from their mouths, and regains the place of its natural enjoyment.

Notwithstanding the voracity of some of these creatures under particular circumstances, their abstinence under others is equally wonderful, if not more so; and this is increased by the fact that long abstinence in them is not attended with the same "falling off in flesh," which is a concomitant of scanty or poor though regular fare in animals of more rapid circulation, and more energetic vital powers. Hybernation is not necessary to this; for turtles and tortoises, alive the while, have existed a year, or even a year and a half, without taking any food; and the turtles which are brought from the West Indies to "banker out the wits" of the ventricular devotees in England, keep their flesh as well by simply tying up the mouth as if they had the free range of their own favourite weed in the sunny latitudes of the Atlantic. Nor is the power of living without food, and, singular to say, increasing in size under this privation, by any means confined to the turtle, or to the reptiles of warm climates. The common newt of our own country will live without food for a month or two; the chameleon and the salamander for more than half a year; that singular creature, the proteus, for two or three years; and the common toad for a period, the length of which has not yet been determined.

The part of the subject which next demands a little of our attention is what may be regarded as the most essential part of the vital system of reptiles, namely, their circulation, and, closely connected with that, their respiration, or the extent to which they require the circulating blood to be purified and renovated by

the access of atmospheric air to it, as it passes through the capillary vessels of the lungs. These must evidently be taken together, because, if the one of them is by any means stopped, the other stops along with it, or at least immediately after.

These two functions, or rather the compound function of which they are the two most essential parts, may be regarded as the indices of the quantity of life—the rapidity of habitual action in the animal, though not of the momentary efforts that it may be capable of making at long intervals. They are purely animal operations, carried on in opposition to physical causes from without, and not in any way by the influence of such causes; and therefore, the more vigorous that the circulation and respiration of any animal are, the better is the animal able to bear the variations of climate and the vicissitudes of the weather. The fact that reptiles are, in the great bulk both of their species and their numbers, confined to the warm lands and seas, and to those places of the lands which have the highest temperature in their atmosphere, might be taken as conclusive evidence that in them the circulation and the breathing must be both very feeble, otherwise they would not leave the animals so much at the mercy of the elements.

Besides the difference in the active parts, the heart and the lungs, there are other evidences in the whole reptile class. First, the whole quantity of the blood is much smaller than in mammalia, or than in birds, though in the majority of these it is less than in the majority of the mammalia; from which we would infer that the voice and the sagacity of animals are in proportion to their quantities of blood. The muscular fibres of all reptiles are white, and they bleed little or none when cut into, if the larger vessels are avoided. They consist more of elastic membrane, composed chiefly of gelatine; and it may perhaps be presumed that this substance is more under the controul of what we may call the electric influence than fibrin, which is a product of blood. Secondly, the change which the blood of reptiles undergoes in passing through the lungs is much less than in mammalia and birds. In these there is a very marked difference between the bright red arterial blood, which is sent over all parts of the body for their nourishment and repair, and the dark red venous blood, which comes back to be renovated in the lungs; but if we examine the blood from these two parts of the system in a reptile, we can hardly tell the venous from the arterial either by the colour or by any other tint. It should seem indeed that there is some intercourse between the solid part of a reptile and its blood, independently of its circulation; for when the animal continues for a long time in a lethargic state, without activity or food, the blood in all parts of the system becomes paler in the colour, as if that portion of it upon which the colouring matter depends were taken up by absorption. Toads, which have been long shut up in the holes of walls, or have been "grown in" in trees, are said to have little or no red colour in their blood. This would lead us to conclude that the system of the blood, which is the controlling system in mammalia and birds, is a controlled system in reptiles; and as the nervous system is always in accordance with the system of the blood, that must be a controlled system in reptiles as well as the other is.

The form and structure of the heart vary a great deal in the different orders of reptiles. In some there is a rudimental appearance of a double heart,

though there is always some internal communication by means of which the systematic and the pulmonary circulations are more or less blended together, so that a greater or smaller portion of the blood, which has been returned to the heart by the systematic veins, can be returned directly by the systematic arteries, without having passed through the lungs. Whether the communications between the cavities are capable of being contracted or expanded, so as to vary the portion of circulation through the lungs, has not been very clearly ascertained; but it is highly probable that these internal communications in the heart contract when the animal is greatly wasted, and expand as it relapses into a state of inaction. This does not of course admit of direct experiment, but it is at least highly probable. Most of the animals that have the double circulation perfect and vigorous are ready for action on the instant; but there is always an effort of preparation required by a reptile; and it is highly probable that this preparation is not confined to the external demonstrations, but that a part, and that the most essential part, goes on within; that in fact it contracts these natural passages of the heart, and, for the occasion, approximates to the character, and thereby acquires a portion, though a momentary one, of an animal with a perfect double circulation. In this again we can learn the indefinite and shadowy place of the reptile in nature, not of the earth or the air on the one hand or of the water on the other, but of the boundary between both. Some reptiles have the heart far less perfect than this, and they are not capable of even momentary displays of energy, but pass their time in an unbroken dullness and repose. It may not be amiss to name the differences in the three orders, leaving out the serpents, as we have done in the other parts.

In the *Chelonia* the heart is broad, and it is nearly semicircular in the turtles, and of a square form in the tortoises; in both there are two auricles, one systematic and the other pulmonary, but they open into one ventricle; this ventricle is divided into two parts by a partition, but there is an opening in this partition which, as we have said, probably varies in capacity.

In the *Sauria* the heart has also two auricles, and as many of these reptiles are active, and most of them can be worked into energy upon occasion, we might expect that the heart should be more complex than it is among the *Chelonia*. The crocodiles are hence the most typical, the most powerful, and the most celebrated of this order, and therefore we shall confine our limits to the heart as it appears in them. It is evidently formed for vigorous action, although that action may be momentary; and the ground upon which we come to this conclusion is very certain—namely, the great strength of the organ, and the power of the muscular fibres with which it is supplied. The auricles are much smaller in proportion than in the heart of the *Chelonia*, but they are far thicker and more muscular in the walls. The ventricle is also very strong, and of an oval form; it is divided into three compartments, which communicate with each other by numerous orifices, all apparently capable of expansion and contraction. The right compartment sends the blood to the hind part of the body, and partly, also through the orifices, into the middle part; the left part sends it towards the fore part of the body, and also in part to the middle compartment, which is the pulmonary portion of the ventricle, and

smaller than either of the other two ; it is this left compartment which receives the blood back again from the pulmonary veins ; there is thus a very complicated circulation in the crocodile—that toward the anterior part of the body approximating the circulation of the mammalia, and that toward the posterior part being more completely the circulation of a reptile ; we may therefore suppose that the fore part of the crocodile is more constantly in readiness for action than that of any other reptile, and this is confirmed by the power and energy with which the animal uses the jaws instantly, and from a previous state of perfect stillness and repose. As the hind part of the animal does not take much share in this ready energy, it follows the general law of reptiles. The motion of the animal is but slow, and whether in the water or on the land it never takes its prey by chase, but always by lying in wait, and in most cases in the water only. The *Sauria*, which live mostly on the land, and are nimble-footed, have not this circulation in the two ends of their bodies ; but the examination of the greater part of them has been so imperfectly made, that it is not easy to trace, in a satisfactory manner, the relation between the circulation and the activity of the animals. This is much to be regretted, and it were earnestly to be desired that able and unhypothesis-bitten physiologists would direct their best attention to the working of the system in reptiles ; for, from the peculiar way in which they are situated on the confines, as between class and class, it is highly probable that they would help us more to a rational understanding of the highly interesting but very serious subject of animal life, than any of those classes which have their locality fixed and definite.

In the frogs and other batrachian reptiles the circulation is very simple. The heart in these consists of only two cavities, one auricle and one ventricle ; it does not therefore appear that they are capable of working themselves up to any degree of energy at all comparable with that of those orders which have the heart of more complicated structure ; and as they have the aquatic structure, or breathe by means of gills, in the early stage of their being, they appear to retain a portion of this character through life ; and hence many of them which are upon the land occasionally, in the warm season, take up their winter abode and pass into the dormant state in the water.

The other branch of this division of the subject is the breathing apparatus. In those reptiles that live and breathe in the water when young, and also in the very few and obscure species which retain this power of breathing along with that of breathing in the air, and which are therefore the only true amphibia in the animal kingdom, the gills resemble those of fishes in their structure ; they consist of a number of filaments around which the water can play, and this appears to be the only form of an apparatus by means of which an animal can breathe air through the residuum of water. Between these and the gills of fish there is, however, a very remarkable difference in the adaptation ; the bone fishes have lids and flaps by means of which they can work their gills ; and even the cartilaginous fishes that have fixed gills, have them in sacs or cavities, which have the power of alternately expanding to receive the water, and contracting to reject it after it has done its office. The gills of the reptiles, whether young or mature, have, on the other hand, no accompanying apparatus by means of which the animal can work them. They are placed on the

sides of the neck without any apparatus or covering whatever, and then the animal cannot work them by any effort on its part ; hence those reptiles which retain them through life are among the most dull of all known animals, and are among the very lowest types of the vertebrated form.

The lungs of reptiles resemble those of the other vertebrated animals in their general structure—that is to say, they are composed of cells into which air may be admitted, and from which it may be again expelled ; but in respect of structure, and of the means of working that structure, they are far inferior to those of the mammalia and the birds. They are in general larger in their whole volume, and extend farther down into the abdominal cavity, but they are lesser in their texture ; their cells are much larger ; they do not, bulk for bulk, expose nearly so much surface to the air ; they are much less elastic in their own structure, and the apparatus for working them are exceedingly imperfect. In the tortoise they are of uniform structure, but the cells are large and few, and the walls or partitions between them comparatively loose and flaccid. In the *Sauria* the lungs, which are in two lobes, one on each side of the heart, there is a sort of double division, or rather division and subdivision, into cells—first they are divided into polygons by large partitions, and then into cells by smaller ones ; but in most cases also those cells have not much elasticity in their walls, and the smaller ones are much larger than the cells in the lungs of mammalia. The lungs of the *Batrachia* resemble those of the *Sauria*, but they are still more simple, consisting of fewer cells ; and they are not developed until the metamorphosis in which the gills are lost or absorbed, these lungs float loosely in the cavity, and, as already hinted, they are in all cases much less elastic than the lungs of other animals. The air can thus much more easily distend them, and thus the animals can inhale a large quantity, or rather passively receive it. In consequence of this, as well as of the less need they have for air, the breathing in reptiles is very slow, and particularly so when they sleep. It appears indeed that, in very many of them, the transition from sleep to perfect dormancy is short and easy. The common turtle will live for four or five weeks, though the mouth and nostrils are both effectually closed. Reptiles will also live much longer than the other vertebrata in the same quantity of atmospheric air, but they will not live in air which is wholly deprived of its oxygen. In what may be called the voluntary taking in of air, which the reptiles, from their capability of suspending their respiration, necessarily possess in a higher degree than those animals which cannot suspend it long, they do not draw it in by the action of the chest and diaphragm like the mammalia ; they *drink* it, that is, they take it into the mouth and gulp it down by the action of the throat, much in the same way as a carnivorous animal gulps down water. The chelonians make way for it by raising the shield at the back part, and depressing the breast-plate at the same ; the first being accomplished by the mere relaxation of the muscles at that part, and the last by the contraction of the same. In short, the two plates work something in the same manner as the boards of a common pair of bellows, only they work slowly and to a very limited extent. The respiration in the *Sauria* is performed by the action of the ribs, the abdominal muscles, and the tendinous continuations of

the sternum, jointly; and in the *Batrachia*, which have no ribs, the abdominal muscles and the integuments perform the same office. The *Chelonia* do not appear to have any other way of taking air into the lungs than by forcibly swallowing it, because they have no part in which the mere pressure of the atmosphere can make a cavity for itself, and therefore they are really the animals which should be called *engoulevants*, or "wind-swallowers," the name which the French give to the goat-suckers, which are capable of getting all the wind they want without any effort in the swallowing of it.

The voice and the temperature of animals both depend on the respiration, though the voice is modified by the larynx. In reptiles that organ is simple, without any epiglottis, though with various ligaments and muscles to the glottis; and in some, the males of the bull-frogs especially, there are membranous bags and cheek-pouches, that serve further to modify the sound. The loudness of the voice depends on the force with which the animal can expel the air; and as the crocodiles can do this with far more force than any of the others, they roar or bellow loudly, and often in the most tremendous key. The *Chelonia* have no such power of respiration, and thus their sounds are only hissing and sighing, and these not very often repeated. Some of the land *Sauria* utter a sort of siffing whistle; while a few, as, for instance, the common green lizard, have little or no voice of any kind.

As to the heat of the animals, it cannot be great, because the heat is in proportion to the action of the system only. Most of them, however, keep their temperature a little above the average of the atmosphere in which they live. They are all very soon affected by cold, but many of them can bear a pretty high temperature: not that there is any salamander, which, like the fabled reptile of the ancients, can live in the fire, and there only; but there are aquatic reptiles in some springs of pretty high temperature. This endurance of heat is not universal, however; for the common frog cannot live in water so warm as the blood of a healthy human body. The change of temperature which takes place during the paroxysms of excessive activity, in those which can be powerfully excited, has not been examined; and yet it is a point the settling of which would be of much use in clearing up the doctrine of animal heat, about which there are still many things not quite satisfactory, notwithstanding all the theories that have been prepared, and all the words that have been written about it.

Closely connected with the vital system in reptiles is their power of passive endurance, and that of reproducing lost members. The first of these is of no inconsiderable value in throwing light on the relation between the laws of dead matter and the laws of animal life; and it is not a little satisfactory that the peculiarities of reptiles in this way extend to chemical action as well as to the action of mere temperature. Analogy would lead us to conclude that this ought to be the case; but a conclusion from analogy is always more satisfactory when we can substantiate it by direct evidence.

We must not understand that it is in its yielding to the general laws of nature, that an animal suffers injury, disease, or death, from those laws, but exactly the reverse. For, if an animal could be so formed as instantly, and without effort or resistance, to obey all

those laws in all their changes, they could have no injurious effect upon it. The only instances which we have, even of inanimate matter, as in perfect obedience to these laws, is in the celestial bodies; and as there is no resistance to the law there, there is no casualty. The sun is not an atom exhausted by its shining, neither is the planet fatigued by its career in its orbit; and could there be any such perfect obedience in terrestrial nature, the thing or being possessed of it, or yielding it, would be totally exempted from death and dissolution. This cannot, however, be the case; because the law of gravitation to the earth always comes in, claiming and forcibly taking a portion of this obedience; and therefore the obedience to no other law, whether of matter as such, or of life, can be perfect. Perfect exemption from these laws has of course the same element of permanence in it as perfect obedience to them; and this is the reason why the immortality of the mind of man is so clear in itself, and in such beautiful harmony with the whole system of nature.

Life is, in its very essence, an opposing of the common laws of matter, whether mechanical or chemical; because the action of life consists in taking a certain quantity of matter from the common stock, and applying it for a longer or a shorter time to the purposes of the animal. It follows from this, by very obvious and even necessary consequence, that the more stubbornly the animal keeps the uniform tenor of its own economy, the more studiously must it have to battle with the changes which take place in physical nature. We have a remarkable instance of this in the human body, which, as it is adapted to the greatest number of purposes, we ought perhaps to consider as the very *chef-d'œuvre* of animated matter. But, though the human body can endure a greater range of temperature than the bodies of most animals, there is no question that it does so with a hard struggle, and in all probability it could not do so were it not supported and buoyed up by mental resource. It is incalculable to what an extent the mental hope sustains the corporeal frailty; for we find that, even under the most favourable physical circumstances, if hope becomes extinct, the extinction of life follows close upon it; and if the body will not die, the agony of the mind makes it lay violent hands upon itself. Yet, notwithstanding all this, and all the resources which the mental sagacity of man open up for him, he is more subject to disease than any other animal. Not only this; for man is exceedingly liable to be injured by the chemical laws of nature, and is much more easily damaged or poisoned than any other animal of the same size.

The other animals have none of this mental hope to buoy them up, and therefore they stand upon less advantageous ground, with reference to the changes of physical nature, than man does. It may be thought that their exemption from mental fear is an adequate compensation, but it is not; for, though there are a few timid individuals of the human race who go about mourning and apprehending all the days of their lives, even when they are in the fullest enjoyment of the bounty of Heaven, and grumbling is of course the blackest and most criminal of all ingratitude; yet they are the very few, and not the many, the casual exception, and not the habitual rule. So that, upon the fair and philosophic principle, the irrational animals are in much worse condition for battling with the laws of physical nature than man

is. It is true that each species of animal has fewer of those laws to battle with than man has, and that it is suited to the circumstances of its locality much better than so universal a creature as man can be suited; but, notwithstanding this, the animal has a disadvantage under changes which man does not, and cannot feel.

In consequence of this, ready obedience to the physical change is always of great advantage to the animal; and this is very clearly shown in the reptiles. Their gelatinous tissues much more readily expand under the action of heat than the more elastic tissues of animals of more energetic systems. The tissue of the lungs has already been mentioned as having but little elasticity, and the same may be said of all those other tissues, for the general character of the animal runs through the whole; and there is not a fibre or vessel in the whole of the working structure which is not sheathed with this tissue. The elasticity resists in proportion to its energy, and herein lies the whole difference of constitutional adaptation between the reptile and the animal of more active system. The elasticity resists both expansion and contraction, and also the irritability of the muscular fibre as such, while the more superior tissue of the reptile at once gives way to any of them.

This variableness of the elasticity of the tissue in different animals is one of the most important points in the whole range of animal physiology; and yet, strange to say, it is one which the professional writers upon physiology have almost entirely overlooked.

It will be observed, too, that this elasticity, though it must be regarded as a product of the peculiar life of the animal, because each animal has it different, according to the nature of its race, yet still it is in itself a property of matter, and not a function of life. If the expression be allowed, and it seems a very allowable one, this same elasticity of the membranous tissue is the anvil upon which the energy of the active principle in the animal hammers out the characters of its various actions; and it would be just as vain to expect that vigorous action could be produced with a readily-yielding tissue, as that a workman could hammer steel into shape upon an anvil of lead. It is the struggle between the principle of action in the animal, and the resistance of the tissue, which is the real cause both of the greater heat of the animal and the greater rapidity of its circulation. The flaccid and yielding membrane will not "show front" to the circulating fluid any more than it will to anything else, and therefore the fluid moves coldly on. So, also, the dull and passive vessel will not contract on the contained fluid and urge it onward, and therefore it lags and loiters.

Applying the general principle to the reptile: it is not thrown into a fever by the ardour of the warmest climate, because the coats of the vessels above give way to the expansion of their contents. On the other hand, the vessel yields to the contracting influence of cold, and contracts so as to stop the circulation, and bring on a dormant state, without almost any resistance, or, at all events, with so little that the system of the creature is little injured by it. It passes into a state of complete repose with very little unpleasant feeling, and no injury to the system; and therefore, as soon as the cause which sent it into this repose has ceased to act, it returns to such activity as may be natural to it at once, and without

having sustained any injury, or undergone any diminution of substance, how long soever the time of inaction may have been. Nay, though it must be admitted that the point here is not so evident to the judgment of "slow-going men," who have but little of the anvil whereupon to hammer their own metal into a weldable condition, is not altogether so clear; it is probable that this very yielding nature of the tissue may enable those reptiles which have the power of momentary effort—of putting on the steam, as one would say—to bring themselves up to the high pitches of excitement under which they always perform their greater efforts. We find that the greater part, if not the whole of them, bring themselves up to this by the inflation or distention of various parts of their bodies, which makes it appear that the tissue must be worked to a great extent before it is able to offer the necessary resistance.

Upon the very same principle, the reproduction of members which have been taken off may be explained. We know that, even in the human subject, a reduced action of the system is absolutely necessary to the speedy cure of wounds or cutaneous lacerations, however slight. If a wounded person, or any one who has a diseased part of the skin, is in very full blood or vigorous action, and especially if under the influence of any unnatural (and in that case not only unnecessary, but injurious) stimuli, is reduced by medicine, or any other cause that lowers the tone of the system, the healing of the wound or the sore is sure to begin, and is perfected in no very long period of time. But if, while afflicted by such a wound or such a sore, the high tone of the system shall be kept up, and especially if it shall be increased by the incautious use of anything of a stimulating nature, then the merest scratch may become an ill-conditioned sore, and that which, in a more quiet state of the system, would have healed without much difficulty, may be turned into gangrenes that will ultimately occasion death.

It really does appear, therefore, that this doctrine of not working the system too hard is one of the most important in the whole of that science which has for its object the promotion of health and long life in animals, whether rational or irrational; and the more energetic, and therefore the more valuable the animal is, the more necessary it is to attend to these particulars. In the case of every animal, and of course of man among the rest, there is a point beyond which heat or cold, or any other kind of physical action, cannot be borne. It is true that there is no absolute place for this point even in the case of the same species, nor do we in very many cases know why some individuals have more power of endurance either way than others; but this does not in the least invalidate the general principle.

The reason of the difficulty of healing a wound or a sore, under strong excitement of the system, is, that the increased and turbulent circulation, restrained by the resistance of the parts which are yet sound, is thrown upon the weak or lacerated part, and destroys the healing action which, in a more moderate and healthy state of things, would be successfully going on there.

We can, without much difficulty, apply this to the case of reptiles, so as to see why they should have that power of reproducing a lopped member which is denied to animals of more vigorous system and more rapid circulation. There is, however, a preliminary

point to which it is necessary to attend, as it helps to throw light upon the more obscure one. If the body is wounded by an instrument, or injured by any virus which is not the production of a vertebrated animal, and we may say not of the mammalia, to which, as a class, the human body belongs, then the wound closes; and though it leaves a scar, more or less conspicuous according to the nature of the wound and the mode of treatment in the curative process, yet there is no absolute diminution of substance; but, on the contrary, the seam of the scar often stands higher than the rest, as if there had been an accession of new substance produced by the injury. But, on the other hand, if a virus, originating in an animal of the same genus, or even the same class, inoculates the body, so as to occasion an inflamed and suppurative sore, there is always a certain destruction of substance, the loss of which is never again supplied. The simplest case to which we can refer is that of a scrofulous ulcer, such as very often breaks out on the lower jaw of persons who inherit that very unpleasant malady, but who, in consequence of the very fact of inheriting it, appear to have the system more excitable, and in a state of more constant excitement than those in whom the body is sound and free from all hereditary taint. This local outbreak of scrofulous affection may be simple, or it may be severe; but, whether it be the one or the other, if it comes to a head and breaks, there is a pit or indication of the destruction of substance left, which is never obliterated or filled up, but which remains with the individual for life. The only other instance which we shall mention is one of foreign inoculation from an animal of the same class, though from one of a very different genus and order, namely, vaccination, originally produced by the matter of a particular disease on the udder and teats of the cow, though now transferred from one human being to another. I this takes effect, the scar which is left in the arm, the usual place to which the virus is applied, the bottom of the scar is always honey-combed, as if portions of the substance had been eaten away by the virus; and if this appearance does not remain after the place has been completely healed, there, to a certainty, the vaccination has not taken effect.

Now, it follows, as proof of one and the same general law, that if the body of an animal, when inoculated with a virus which occasions an unusual action of the system, prevents that restoration of a small quantity of local matter which would have been restored to the full if the action of the body had been in its usual state; much more must a system of circulation, which is naturally very slow, admit of the reproduction of a member which could not be reproduced with a system of greater activity. Therefore we are to attribute this curious reproductive power in reptiles to their slow circulation as the immediate cause; though, carrying the matter a little farther, this again resolves itself into the readily-yielding nature of the tissue, and the gelatinous nature of the whole soft parts of the body.

These reproductions of parts have been seen in natural cases, and they have been brought about, or rather, scope has been given for the bringing of them about, by some of the most scientific and careful enquirers into the animal economy, such as Spallanzani, Bonnet, and Blumenbach. The experiments were made on the nimble lizard and the water-newt, and they were performed both on the limbs and the

tail. Very soon after the separation of the part there is an effusion of blood, though a very slight one, as might be expected from the comparatively small quantity of blood, and the closeness of the circulation in these animals. The wound soon heals without any external application, or even the protecting of it from the action of the air, which does not appear to retard the healing process in these animals of slow circulation. Soon after the healing, the new member begins to sprout, and grows to the proper form and size in a longer or a shorter time, according to the nature of the animal, though, for a considerable time, the new member looks much more delicate than those which the animal possessed from the beginning. This power of reproduction is not confined to what is called the extremities, as, for instance, the tail and the limbs, for it extends also to the most delicate and nicely-formed of the organs of sense. Blumenbach dissected out the eye of a water-newt, which was, in due time, replaced by a new eye as perfect in all its parts as that which had been removed.

The external coverings of reptiles are also worthy of attention, as they are peculiar, and differ not from those of any other of the vertebrated animals. This, as in other vertebrated animals, consists of three parts: an *epidermis*, or cuticle, or scurf-skin; a *dermis*, or cutis, or true skin; and a *rete mucosum*, or mucous tissue.

The two more internal of these do not differ very much from the same integuments in the other vertebrated animals, excepting perhaps in some of the *Batrachia*, as for instance the frog and the toad, in which the cutis is attached to the parts underneath at only a few points, and loose like a sack at all other places. This is not, however, peculiar to this batrachian reptile; for we find instances of it in other classes of animals, as for instance in the gannet among birds (see the article GANNET in this work). The object of this general detaching of the skin from the parts under it, except at a few points, which serve as ties or anchorings to keep it from shifting from its proper place, appears to be that the skin may admit of inflation by the introduction of air, without disturbing the economy or action of the other and more essential parts of the animal.

The epidermis, or cuticle, is much more varied in its appearance and appendages; and these are among the means used for distinguishing them. The horny productions of this part, to which the names of scales or shells are given, are productions from the exterior of the epidermis, just in the same manner as the hair and fur of mammalia, and the feathers of birds. None of them, however, are true shells, or even crusts, such as occur in the shelled mollusca and the crustacea; for they consist of consolidated animal matter, without any salts of lime; and they are always external of the epidermis, and not within it, as are the shells of the mollusca. Of these the most remarkable are the horny coverings of the *Chelonia*, which are known as "tortoise-shell," "turtle-shell," and other names, according to their quality, which depends upon the species by which they are produced. Though we say that these productions are "horny," as distinguished from bones and shells, both of which have the carbonate or the phosphate of lime, or both, in their composition, we must not confound them with the form which is found in the horns, hoofs, and claws of the mammalia, and in the

beaks and claws of birds, or in the nasal armature of the rhinoceros. All these are of a substance very nearly of the same nature as hair or feathers, and always of a fibrous texture, capable of being divided longitudinally into threads or fibres. All the appendages to the mammalia, and generally also to the birds, are much more easily split longitudinally than they are divisible in the cross direction. This is perhaps more strikingly the case in the nasal horns of the rhinoceri, than in any others; but it holds in all of them that can be considered as the products of an epidermis capable of producing hair or feathers under other circumstances. The same character holds in the plates of baleen, with which the mouths of the whalebone whales are armed—all clearly showing that, if the general habit of the class of animals is to produce a detached fibrous covering, that covering when it comes in solid portions will follow the same general law. It must not be supposed that the broad antlers of the hinds of deer are an exception to this, for they are really not horn, though they are called "horns:" they are bone, the produce, not of the epidermis of the heads of the animals, but of the bones of the same.

There is not the slightest tendency to the production of hair, wool, or any other fibrous matter in the epidermis of any of the reptiles; and, therefore, the appendages to their skins, whether they be great and strong plates, as in the *Chelonia*, or scales of various sizes, as in the different genera of the *Sauria*, are never of a fibrous structure. They have various degrees of hardness and tenacity; but they will break nearly equally in all directions, and they are not subject to those markings by the application of heat which apply to true horn. This, besides its beauty, is one of the recommendations of tortoise-shell as a material in some of the ornamental arts.

But it must be admitted that even in the *Chelonia* the solid plates are produced rather from the cutis, than from the cuticle; for although the body within them is invested in a very perceptible cuticle, there is also another fine membrane without; so that, if the expression may be admitted, the shield and breastplate of these animals are produced between the folds of a sort of double epidermis. If the matter, which we call the shell, is very strong and compact, as it is in the greater part both of the land tortoises and the sea turtles, then the membrane over it is very thin, and apt to be obliterated; but, if what we call the shell is of a weaker consistency, then it is covered with a tough and strong leathery envelope; and it is not a little worthy of remark, that the turtles which have this soft and pliable shell and leathery covering are by far the most active and ferocious of the whole order.

In most of the *Sauria* there is the same complication of the integument. There is one epidermis investing the true skin; upon this there are scales or horny tubercles of some kind or other, and over these again there is a second epidermis. The crocodiles and some others have broad horny plates, and others have the scales distributed in bands, variously disposed on the different species. The *Batrachia*, in general, have the skin soft, and without any horny or scaly appendages; and although the old and foolish fable has it that there is a hard substance in the envelopes of the head of the toad, which has great medicinal virtues, the saying, like many others of the same sort, is totally without foundation.

In the *Sauria* there are often very powerful muscles immediately under the skin which can produce considerable motion in that, while they show the close connexion which it has with the parts underneath. In the *Chelonia*, both the shield on the back and the breastplate on the under part, consist of a number of pieces, which contribute much to the strength of the whole. These, in some cases, touch at their edges, and, in others, they overlap. The shield or upper defence is the more perfect of the two. It consists of a separate row of plates or separate pieces, more or less firmly attached to each other, which form the middle or central part, along the mesial line of the vertebrae. Immediately in contact with these at the sides there are others, which with them make up the disc of the shield; and external of these there are still others which compose the margin, and approach the sides of the breastplate. This shield on the back of these reptiles is united to the breastplate on the under part only at the middle of the sides; and separate at the fore and hind parts, for the action of the head and fore paws at the former, and for that of the tail and hind paws at the latter.

It does not appear that, under any circumstances, the *Chelonia* ever change the coverings of their bodies; but the *Sauria* and *Batrachia* do, especially when they are in the young state. In them, however, the old skin is not cast at once, as it is in the *Ophidia*, of which we shall speak in another place; for it comes off gradually in patches, and the animals are not so much weakened by the operation as those are which moult the entire covering at once.

The mode of reproduction in animals, and the number of their young, are points of great importance both in understanding their own physiology, and in tracing their connexion with the rest of nature. Reptiles of all orders are in two sexes, without hermaphrodites. All the *Chelonia*, *Sauria*, and *Batrachia*, with the exception of the salamanders in the latter group, are oviparous; and the number of their eggs in a season may much exceed those of birds. They do not, however, pay much attention to the eggs after they are extruded; and, therefore, both eggs and young fall a prey to many enemies. The eggs of the *Chelonia* and *Sauria* resemble the eggs of birds, only there is much less lime in the shell, and the white is gelatine, not albumen, so that the eggs do not boil hard. The eggs of the turtles are much esteemed as food, and those of the crocodiles are said to be nutritious; but they have a musky smell. All reptiles which are produced from eggs with a firm covering come out of the shell in the same form which they are to preserve during their lives; and it does not appear there is the same limit to their subsequent growth as is found among mammalia and birds. The *Batrachia* undergo a metamorphosis, and some of them have curious modes of bringing the eggs to maturity, an account of which will be found on looking back to the article Frog, in this work.

We have already casually alluded to the readiness with which all reptiles yield to a reduction of temperature, and pass into the hibernating or dormant state. The readiness with which they pass into this state, under comparatively little reduction of temperature, is a great advantage to them in the way of preservation. The effect of reduced temperature, equally affecting all its body, and accompanied by abstinence from food, is to produce a tendency to the dormant or hibernating state in every animal; only

the longer that the animal can resist, it receives the greater injury from the change of state, and, consequently, has the less chance of awakening to life; in as far as evidence on such a subject can be collected, we believe it may be said that the first symptom of a fatal nature, which occurs to those who perish in the snow, or are recovered when they have nearly perished, is a heavy sleepiness, from which they become at last quite unable to keep themselves awake. If only a small portion of the body is exposed to this extremity of cold, while the rest of it is kept comparatively warm, then the action on that part becomes a topical disease, which ends in the destruction of the part. This resistance in the whole or part of the body is clearly owing to the natural elasticity of the membranous tissue, which cannot, without long and severe action of the cold, be made to contract the vessels, so as to stop the circulation. In reptiles the necessary vascular constriction is produced by a very slight degree of cold; and thus they are not in the least injured by it. Several of the mammalia also hibernate, of which the bats are, perhaps, the most remarkable instance; for in cold countries they disappear for nearly as long a period of the year as reptiles do in temperate ones.

When there is little or no difference of seasons all the year round, there is no necessity for the hibernation of reptiles; but whenever there begins to be a perceptible difference, hibernation is sure to occur. In North America the reptiles hibernate as far to the southward as the shore of the gulf of Mexico, though some part at least of the vegetation there is of a tropical character.

Each species seeks a peculiar retreat in which to pass the season of temporary death. The aquatic *Chelonia* bury themselves in the mud; and the land ones in the earth, the crocodiles bury themselves in the sand or other banks; and the *Batrachia* hide themselves in holes, or seek the mud under water. The progress of this is gentle and gradual; but the state itself, however, in the severe weather, very complete. Nothing will rouse them but the application of heat; and that application must be gradual, otherwise the consequences are injurious, if not fatal. While they are in the depth of their hibernation, the suspension of all the animal powers is as total, though of course not so final, as if they were dead. No mechanical action and none of the ordinary chemical actions have any effect upon them. They may be torn, cut to pieces, burnt with acids, or acted upon in various other ways, without showing, by motion or in any other way, that they have the least feeling of what is done to them. Whether, by unequal exposure to the cold, which many of them must experience, particular members of their bodies are liable to suffer, as certain parts of the human body do when they are frost-bitten, has not been very clearly ascertained; but it is probable, and may be at least one of the uses of that reproduction of parts with which they are endowed. We believe that a seasonal state of dormancy takes place in all or in most reptiles, whatever be the temperature of the country in which they are found, and that it is, in all cases, a total repose, not attended with the slightest diminution of the weight or impairing of the strength of the animal. When the proper action of external nature comes round they again gradually awaken, and resume all their functions as if nothing had been the matter, but rather as if they were refreshed by a

sound and long-continued sleep. As this seasonal repose, which reptiles enjoy, is complete rest to the whole of their system, whereas the sleep of other animals is rest to the system of sensation only, and not to the vital system, the reptile has the advantage of the other animals, and awakens much in the same condition as a creature actually new.

What we have stated are the leading facts in the structure and more general habits and action of the three orders to which our consideration has been directed. Though they vary much from each other, and cannot be said to follow any one class and precede another, in anything like a regular chain of being, yet they follow the general type of the quadruped, or animal with four limbs, to whatever purpose those limbs may be applied, until it appears to merge in the type of the fish, in which class the form is gradually obliterated.

Having done this, we shall now very briefly notice the remaining order, the *Ophidia*, or snakes and serpents, which do not properly range with the others in the structure of their bodies, although they clearly belong to the class of reptiles. They stand in the same anomalous relation to the general class of reptiles as the marsupial animals do to the common mammalia, only the anomaly in these is in the mode of reproduction, while in the serpents it is in the general structure of the body. There is another circumstance worthy of notice before we proceed to the outlines of the structure; and that is, that most of the serpents, which retain within the integuments slight rudiments of extremities, chiefly of anterior ones, the mode of production is simply oviparous, like that of the *Sauria*, while in the poisonous serpents it is ovoviviparous, as it is in the case of the salamander among the batrachian reptiles; but there are none of the *Ophidia* which have the same mode of reproduction as the more typical *Batrachia*, the common frog, for instance.

To detail the general form of a serpent would be superfluous. It consists of a head, a body, and a tail in one lengthened bone without any extremities, though there are sometimes membranes to the head or neck, which admit of being inflated at the pleasure of the animal, which inflations appear to answer a purpose in the economy of the animals having them, to which we shall have occasion to revert.

The skeleton is simple in them, consisting chiefly of the skull, the spinal column, and the bones of the head. The skull is small, as in the other reptiles, and the brain is also small and very imperfectly developed, so that the idea of a serpent of any kind being the emblem of wisdom or cunning is without foundation in the nature of the animal. The mouth is the chief organ for taking the food in all serpents; and it may, in every case, be considered as a prehensile instrument, and not a killing or wounding one. The bite of a serpent, considered merely as a mechanical operation, cannot be regarded as very formidable, even in the case of the largest and most powerful of the order, though the action of the poison-fangs, which is a mere puncture and not a bite, not necessarily drawing blood, is often of the most deadly character, and it is at all times painful and dangerous, especially if the animal upon which it is inflicted has a diseased habit of body.

The mouth being thus a seizing and swallowing mouth, and not in any respect a mechanically wound-

ing or masticating one, is of course constructed in all its parts for the work which it performs, and being so, tends to disqualify it for performing the opposite kind of work. The under jaw, as in birds, is made up of two maxillary bones; and these are not articulated upon the bones of the head as in the mammalia, or on the upper jaw as in the crocodile, but upon an intermediate bone on each side, resembling the *os quadratum* in birds, both in situation and in use. The union of the upper jaw with the cranium, though not an articulation, is very loose in all the species; and, in some of those that swallow large prey, it has nearly all the flexibility of a joint; and, as the tendinous or ligamentary connexion is flexible every way, even this jaw is capable of twisting motions. This flexibility at the junction of the upper jaw with the cranium may be considered as serving fully as much in removing the skull and its contents out of the way of any very large prey which the animal may have to swallow, as in merely widening the gape, for which the organisation of the jaws themselves is abundantly sufficient. In the most remarkable of the swallowing serpents, the great python of south-eastern Asia and its isles, the mastoid extends backwards very considerably in rear of the articulation of the head with the neck, and to such a distance that there is twice as much length behind the orbit of the eye as there is between that and the intermaxillary bone at the point of the muzzle. To the under side of the extremity of the mastoid, the *os quadratum*, or trunk bone (*caisse*), is articulated, the articulation being on the same part in the orbit, when the jaws are in a state of repose. In this state the *os quadratum* stands in a perpendicular direction, and the lower jaw is articulated to its under extremity. The bone is not so long in proportion in the python as in some other serpents, but it is, and indeed all the bones of the mouth and jaws are, very strong. Each jaw may thus be said to be articulated upon one extremity of this connecting bone, so that while the lower one opens forward or downward upon it, the upper one moves forward and upward. The opening of the mouth is therefore extended to the full measure of both jaws, together with the two connecting bones, which furnishes a gape of very large dimensions. About one-half of this vast circumference is margined with very powerful conical teeth, considerably bent backwards and a little inwards, but with the short points a little round, so that they the more readily take hold of any substance. In the lower jaw there is only one row of these teeth, but in the upper there are teeth on various parts. There are four small ones on the intermaxillary bone; fourteen in each side, in the external row in the maxillary, and three small ones in the anterior part within these, as a second row. Then there are six on each of the palatal bones, and eight on each of the pterygoids, forming a continuation which reaches very nearly to the opening of the gullet, which opening can be extended to the full width opened by the circle of bones in the mouth, when brought to a plane, which is of course the position in which they form the most ample circumference. There are thus altogether one hundred and four teeth in the upper jaw, and there are thirty-six in the lower, making in all one hundred and forty teeth, and teeth of a very formidable character in the way in which they are intended to act, in the mouth of this mighty monarch of the pestilent swamps of the oriental isles. Of its other power,

that of crushing very strong animals in its folds, we shall speak afterwards.

In those serpents which kill by poisoning, the mechanical armature of the mouth is of a less formidable character, though in them also the gape is of large dimensions for the size of the animal. The rattlesnake will serve as an illustration of these. The mastoid is much smaller than in the python, and the articulation of the *os quadratum* is not farther back than that of the head. That bone is long and slender, and in a state of repose inclines backward at its lower extremity. The under jaw is longer than the upper, and considerably bent, with the concavity upwards. The palatal and pterygoid bones of the upper jaw are bent in the contrary direction.

The only teeth which appear fully developed in the upper maxillary bones are the poison-fangs, one on each side near the anterior part of the bone; but there are others behind them, at least in some cases, which could take the place of those in the event of their being broken or lost; these are hollow, with openings near the points, from which the poison is discharged. When the animal is in a state of repose these deadly weapons are concealed in folds of the integument. They are not, however, folded down by an articulation on the maxillary, for they are firmly set in that bone, and indeed could not act so well were they jointed at their roots. The short maxillaries in which they are inserted have a motion on the transverses; and two muscles, which have their origin on the other bones of the jaw a considerable way backwards, are inserted into the upper part of the maxillary, so that when they contract they turn the bone by pulling the upper part of it, and the advance which this causes elevates the poison teeth, or fangs as they are called. The same muscles pass one on each side of the poison bags, and compress them at the same time that they elevate the fangs. The pulling back of the upper part of the head of the bone also shortens the poison duct, and thus enables it to give way, by an enlarged diameter, to the passage of the virus. Thus these serpents always infuse their poison into any wound which they make with their fangs, as the very same muscular apparatus works both the fang and the poison. The transversal bones, which are very long in these animals, have a bend upwards, so that they are out of the way of the poison apparatus: and the bend downwards of the palatal bone at the middle part conduces to the same purpose, by preventing any thing against which the roof of the mouth may press from interrupting the flow of the poison. The increased depth necessary in the anterior part of the maxillary, for allowing the fangs to be lowered and raised, gives more apparent size to the muzzle in the poisonous serpents than is possessed by those which are not poisonous. The swallowing teeth of these serpents are few and of small size, as compared with those of the species which have no poisoning apparatus. They in general consist of a single row of small teeth on each side of the lower jaw toward the front, and another row on each of the palatal bones; but there are none on the intermaxillaries or the pterygoids; and, with the exception of the poison fangs, the mouth is not a formidable one, either in the strength of its bones, or the number, size, and character of the teeth with which it is armed.

A question has sometimes been raised as to the use of these poison-fangs in the economy of the ser-

pents which have them, whether they are to be considered as principally intended for killing the prey on which the animals feed, or for defences against their enemies. Some have thought that they are principally of a defensive character, but this is contrary to the general analogy of nature, and also to the appearances of the particular case. Poisonous serpents are all, without exception, carnivorous; and, according to the accounts, which, though they may be exaggerated in many points, are surely not wholly fictitious, their prey is much more alarmed at their appearance than the prey of other serpents more powerfully armed in the way of teeth, and also of greater activity. But it is a pretty general law of nature that no carnivorous animal is furnished with any organs, the primary use of which is that of defences, or even weapons of war: talon, teeth, or fang, whatever the weapon may be, its leading use is always of a predatory character, and the grand purpose which it serves is invariably the feeding of the animals. No doubt such animals do use their weapons in warfare, both on the defensive and in the offensive; but this is a secondary use of them, not essential in the economy of the animals, and not resorted to for any occasion, unless it is absolutely necessary. The animals which have defences that are not of essential use, or of any use to them in their feeding, are animals which are preyed upon, and not preys. In most of them too their weapons are used more against their own species than against enemies. The males of almost all the horned animals fight with each other in the rutting season; and in the elephant the tusks are not even the grand means of vanquishing an enemy. Making a lurch on the enemy, shaking him off by the action of the subcutaneous muscles, and trampling him to death after his fall, are the chief modes of defence with the elephant.

But if animals which, both from their nature and their haunts, are very much exposed to enemies, have not defences absolutely for their protection, why should we suppose that these should be given to rattlesnakes and other poisonous serpents? From their haunts and their habits, they are among the animals that have the least chance of annoyance from any enemy save man. The greater part of their time is spent in the fastnesses of bushes, brakes, and other covers, where enemies are not very likely to reach them; it being understood that birds, and not mammalia, are the principal enemies of the serpent tribe. The idea that the deadly fangs of these animals are defences must therefore be abandoned, and they must be considered as conducing to the more humble purpose of enabling them to eat their dinners, which are few and far between.

It must not be supposed that this is a piece of merely gratuitous criticism on a subject of no great importance in itself, for really it involves the subject of a very mischievous tendency in the study of natural history. The error lies in this, that there are really "weapons of war," created purposely in nature; and this being once admitted, it follows, of course, that war is a part, and a necessary part, of creation, and that, as such, it is not only unavoidable, but natural. Now, no doctrine can be more false or more mischievous than this. For there are no evils in nature; and war is not only an evil, but the very worst of evils; and therefore war is not a part of the law of nature; it is a direct breach of that law. No animal but man engages in war as a trade, though

animals do fight; and man engages in it only in consequence of having broken the law of nature (as given to him), and become wicked.

The use of weapons against their own species, which we find in various animals, though it does not in any way conduce to the feeding of the individual, as the use of the weapons of predatory animals always does in their natural and original exercise, must not be supposed to conduce nothing to the advantage of the species. It is the males of such animals that are pugnacious; and it will be found that the very pugnacious ones are invariably polygamic. The purposes of it seems to be the preserving of the race in the very best condition as to the size, strength, and vigour of the successive generations. We know that, in the case of hybrid animals, the form, the size, and the strength, follow after the male parent; and the breeders of domestic animals know this to be the fact, and rest upon it with practical advantage. It is by proper attention to the males that the breeds of our domestic animals have been so much improved since breeding became a science. On the other hand, where no attention has been paid to the good properties of the males, the breed has become stationary, and in many cases degenerated. The pugnacity in wild nature, in consequence of which the more powerful male drives off all the more feeble ones, appears to answer, in wild nature, merely the same purpose as the skill and attention of the breeder answers in art. Such wrong notions of the use of organs, as that which we have been endeavouring to expose, tend greatly to spoil the useful information which we can so copiously obtain from the rational study of animated nature.

The poison is very much of the consistence of a solution of gum, to which substance it bears a resemblance in its general properties; but whether the poisonous nature of it is owing to the presence of a poisoning ingredient, or arises from the mere composition of the entire substance, it is not easy to say, though we know that there are some chemical compounds which are quite harmless when the several ingredients are in one proportion to each other, and deadly poisons when that proportion is different. The virulence of their action, however, is not destroyed by their being dried, which is a proof that the deadly part is diluted in order that it may flow more easily along the duct and the fang. It might therefore be used to poison weapons, in the same way that compound poisons are used by the inhabitants of warm countries. In the vegetable poisons it is now generally understood that the deadly part is an alkali, and it is possible, but not hitherto fully established, that the same may be the case with the animal poisons.

Whether the coincidence is accidental or not we pretend not to say; but it is a coincidence worthy of remark, that the places of the world in which the inhabitants are most in the habit of poisoning their weapons both for the chase and for war, are also those in which the poison of serpents is the most deadly, and the vegetable poisons the most numerous and virulent. The rich and warm parts of tropical America, and the oriental isles, are the remarkable places for all the three; and we believe there are few places containing naturally a very poisonous reptile in which a poisonous plant may not also be found.

Poisonous serpents vary in their deadliness with

the species, the condition of the animal at the time of its infusing the poison, and also with the part of the body upon which the wound is inflicted. If the poison is introduced into a vessel of any considerable size, death, even in a large animal, very speedily ensues, especially if the reptile is in a very healthy and vigorous condition, and has not been using its fangs for some time previous. A puncture in a part where there is no large vessel is not so speedily mortal, but it is attended with far greater pain and suffering to the unhappy victim. Even if there is a recovery from an inoculation of this kind, very unpleasant symptoms are felt for a considerable time after the accident.

As the consequences of these inoculations are often of the most distressing kind, and valuable lives are often perilled by them in a moment when such a casualty is the least apprehended, remedies for them have always been highly desirable, and many have been proposed. Such as are always at hand, and can be promptly and easily applied, are of course the most valuable; because the poison gets so soon diffused over the system, so as to defy not only all local but all general means of relief, that the utmost expedition is necessary. It has been proposed to cut down upon the part to a greater depth than the fangs have entered, and to cut freely. Then instantly upon the incision being made, to apply the mouth and suck out the natural fluids and the poison together. In preparing to do this it is much more valuable to divide the veins and other returning vessels than those which carry the fluids from the centre of the system, because it is by the former that the poison most speedily reaches the vital parts and affects the whole system. The sucking may be performed without any danger, if no part of the interior of the mouth is wounded, for these animal poisons are perfectly harmless when applied to the unbroken integuments. If there were no sore or broken skin upon the hands, we might wash them in the poison of the most deadly serpent with as much safety as they could be washed in water. Another topical means of preventing the poison from getting into the system is to bind the part so firmly with a ligature as to cut off all connexion between it and the body. Of course this can be adopted only when the bitten part is one to which a ligature can be applied, and unless the application is instantly made it has but little chance of success. In extreme cases, however, it is desirable that every remedy which has the slightest chance of success should be applied. Ammonia has also been recommended both externally and internally; in the latter case to bear up the system against the feelings of horror and prostration which the poison produces. Caustic potass has also been recommended as a topical application; and many vegetable substances have been recommended as specifics. But there is some doubt as to the efficacy of any or of all of those, as the precise mode in which the poison acts upon the system, is not known. The subject is, however, one of very great interest, and information respecting it, obtained from experiments skilfully made and faithfully reported, is very much wanted—the more so that, in the vulgar opinion, the subject has been invested with horrors which certainly do not belong to it, bad as it is in itself; and there are probably many who die of the bites of serpents from the mere force of the belief that no one who is so bitten can recover.

The next part of the structural character of serpents which draws our attention is their mechanical action, whether considered as merely conducing to locomotion, or as one means of securing and overcoming their prey. The first thing to be considered in this is the very peculiar structure of the vertebral column, which, in its articulation, and in the mode in which the ribs are attached to it, is different from that of any other animal.

There is a resemblance in the species of all, but the most perfect form is found in the great crushing serpents, which kill their prey by compressing it in their folds. The articulation of the head with the body is by means of a single tubercle, but this tubercle has three distinct articulating surfaces like an irregular pulley, and therefore, though it has a very free lateral motion; it has but little in any other direction. The posterior extremity of each of the vertebræ is formed into a rounded head, from which springs the main body of the vertebra, increasing in diameter, and terminating in a shallow cavity, which receives the round head of the one preceding it. From the neck of the round head of such vertebræ as have ribs attached to them, there spring two lateral processes, one on each side, which curve outwards and a little downwards and increase in diameter as they proceed, each ending with a double tubercle placed longitudinally; and to this the cavity of the rib is applied. Upon the dorsal aspects of the vertebræ there are also short spinous processes which afford points of origin and insertion to the dorsal muscles. The ribs are awl-shaped and tapering to points, and very strong and elastic for the quantity of matter they contain. They do not meet each other on the under part of the body, neither are they in any way united to a sternum, for there is none. Each pair, for there is a pair on each vertebra, are united at their points to the two extremities of one of the *scuta* or shields on the under part of the body; and as the ribs are articulated by cavities on the tubercles of the lateral processes, and are furnished with a curious array of five differently shaped sets of muscles, they admit of a very great deal of motion. The first set of these intersected muscles pass obliquely from one rib to the next. The second pass over two ribs, and unite the external ones of each four in a direction nearly parallel to the spine. The third set also pass over two ribs, and unite the external ones of four, but they pass very obliquely from near the articulation of the one to near the point of the other. The fourth set pass over one rib, and unite the first and last of these in nearly the same direction as the second set. The fifth set unite rib and rib in a direction parallel to the spine, they are very numerous, and extend between rib and rib something in the same manner as the rounds of a ladder.

These intercostal muscles alone form a very complicated apparatus, and are capable of producing more motions than it would be very easy to count. When to these we add the muscles which are inserted upon the spine itself and its dorsal processes, we are constrained to admit that there is not in the whole of animal nature, wonderful as many of the structures are, any piece of mechanism superior, and few equal, to that of the spine and the ribs of a serpent, with their apparel of muscles. The bones too are articulated in such a manner as to give the fullest latitude of action to this very complicated but very beautiful mechanism.

Cobra

Rattle Snake

Crocodile

The number of processes to which ribs are articulated vary in the different genera. In some they are as many as two hundred, or even more, and as far as they extend may be considered as the body of the reptile. The vertebræ of the tail are without processes for the ribs, as there are of course no ribs there. The processes on the dorsal aspect of that member are also more simple and more uniform in their shape than those on the dorsal aspect of the body. They are little else than simple tubercles in all the species, while those on the back are at some distance apart in the crushing serpents, and nearer to each other in the poisoning ones. The ribs may be considered as a sort of legs to the reptile, and the plates or shields on the belly as feet; but before we can explain the action of them, we must say something of the covering of the body.

The power of action in the muscles of those animals is as wonderful as their structure. They appear to have to bring themselves up to a certain degree of excitement before they can act with their full vigour; but when they have done this, their starting into vigorous action is without parallel among animals. When one of the more powerful crushing serpents is stimulated by hunger and the sight of prey jointly, its attack is more like a discharge of electricity than any thing else. It does indeed take some time in working itself up to the necessary pitch of excitement; but the instant that it has done this the victim is awakened in its folds in such a way that one can hardly tell how it is done, even though standing close by. The gripe of the folds is also tremendous; for it has the power of tightening them by crawling along the skin by the action of the ventral plates, and as, in doing this it has as many points of holding as there are plates, it pulls and tightens as a rope would do if drawn by a powerful engine; indeed it does more than this, for it draws in every part of its length at the same instant. A dead substance which is thickly set with barbs will work onward in a wonderful manner. One of the barbed beards of barley will very soon get from the waist to the shoulder of one who is working at that species of grain; and the operation of felting, in the making of hats or otherwise, and the milling of woollen cloths, are other instances. These are, however, only dead matter, urged on by mechanical force; while the creeping motion by which the serpent strangles its prey, and even crushes the bones, is a living power which operates at every point where it touches, and there is really nothing in the mechanics of dead matter that can be brought in illustration of it. The power of what seems to be but a small serpent is very great in this way, and can crush to death an animal, around which it appears nothing but a rope of moderate thickness. It does not fasten indiscriminately, especially if the prey is large, but concentrates its coils at that place where their gripe is the most effective for its purpose. It is probable that the exertion of gripping the prey to death in the folds, conduces to the secretion of that slimy matter which so much facilitates the swallowing of an animal many times the diameter of the swallower. But we have already mentioned the extent to which the gape can be dilated; and there is hardly any limit to the dilatibility of the gullet.

It has sometimes been said that these crushing serpents break the bones of their prey by straining it against a tree; but it is doubtful whether it would

not lose much more than it gained by such a means of assistance. It is in its coiling round and round the body of the prey, and performing the tightening motion by means of the scales, that the vast crushing power of this animal consists; and if it were to be coiled round any thing else along with the prey, it is easy to understand that its force would thereby be interrupted in the continuity of its action, and consequently lessened in its effect. In the case of small prey, this terrible crushing power is not put in requisition, the gape is quite enough to make them find their way to the gullet; and though it is any thing but a pleasing sight, it is certainly a curious one, to see one of these serpents making a mouth for the devouring of a fowl or rabbit, or any other little animal.

The reverse of this operation is also a powerful one; though it is momentary, and does not partake of the curious creeping into close folds, which is the grand part of the crushing. The reversal of the twine round is the other motion, in which the whole muscles are brought into play, and it is practised by many serpents whether they crush their prey, poison it with the fangs, or simply swallow it. Generally speaking, the body is coiled up in circular folds on the surface of the ground, with the tail at the circumference, and the head at the centre, and elevated above the coils when the animal is alarmed or excited. It does not at once start from the coil, but opens its mouth, glares with its eyes, sends out its pestilential breath, beats the ground with its tail, and makes a noise with its rattle if it happens to have one. After it has worked itself into a sufficient degree of excitement, and there is reason to believe that in doing this both the heat and the quantity of breathing are brought up to more than the usual pitch, it makes its spring as if it were an arrow shot with great force from the bow of its own folds. In this it is careful not to throw away its effect, which is a considerable one; and as it appears instinctively to judge with accuracy both of the direction and the distance, it seldom misses. Of course it depends on the character of the species, in what manner it acts after it has sprung. If it is a crushing serpent, it twines; if it is a poisonous one, it uses the fangs; and if it is merely a swallowing one, it darts open-mouthed upon the prey, and gulps it down upon the spot. Serpents of this last description generally prey upon smaller animals in proportion to their own size than the others do; and it is also highly probable that the poisoning serpents swallow their small prey without making any use of the poison-fangs.

It now remains to notice the progressive motions of the serpents on their ordinary march, and when they are not under any extraordinary excitement; but in order to do this we must previously notice the covering of the body.

The skin of serpents consists chiefly of two parts—*dermis*, or skin properly so called, and the *epidermis*, or cuticle. The dermis is without any callous surface, is of considerable thickness and great strength; firmly connected to the tissue of muscular fibres underneath, and never cast. This skin is very gelatinous; and, when properly tanned, that of the larger ones makes remarkably thick, tough, and durable and excellent leather, only the surface of it has a curious appearance from the impressions of the scales. The epidermis is cast every season. The appendages to this skin consist entirely of scales. There are two

N N

distinctions as to these scaly appendages, which are accompanied with differences both in the characters of the animals and the styles of their locomotion. Those which have the same kind of scales upon the upper and the under part of the body, may all be considered as quite harmless; and, unless to the very small prey on which they feed, they are among the most innocent and gentle of all living creatures. In those the *ossa-quadrata* are articulated immediately upon the cranium, without the intervention of mastoid bones; and the upper maxillaries are united to the cranium and the intermaxillaries, so that the width of their gape is limited. Their ribs also do not in any way act as legs, so that their progressive motion is performed by flexures of the body. They are quick and gliding in their motions, and can in general move with either end foremost. They advance into higher latitudes than the others. They are not in fact true serpents, but snakes; and they ought not to share any part of the suspicion which attaches to the others. The hard coverings of their bodies are true scales. Some of them have a third eyelid like the *Sauria*, and slight rudimental traces of scapulars and clavicles, though not even a vestige of anterior extremities.

The true scales upon all serpents are placed lengthways, and pointed or rounded at their posterior extremities, in which they differ from the scuta or shields which are on the under part of the true serpents. These are placed crossways on the belly, and attached at the ends to the two ribs, which are articulated on the same vertebra, as already noticed. They are continued on the under side of the tail, sometimes only in one row, and sometimes in two; and in all the species that have them, these shields may be considered as answering the purposes of a sort of feet. When these serpents move at their full speed, they do it by forming the body into successive arches, the scales behind the arch holding on till the extending of the arch advances the fore part of the body. In their slower marches they literally creep along with hardly any flexure, and it is this which forms their characteristic style of marching. One of the actions of the muscles attached to the ribs depresses the anterior part of the shield and raises the posterior, so that it takes a hold on the ground. By this means, also, the anterior edge of each shield can get on below the posterior one in advance of it, by which means another muscular action is enabled to shorten the distance between shield and shield, over a considerable portion of the under side of the animal. The more that the distance is shortened, the more the posterior edges of the shields are raised, and they take the firmer hold of the surface over which the animal moves. Thus, by holding on with the hind part while the fore part is advanced, this curious method of walking by means of ribs and shields, instead of legs and feet, is carried on with great ease, and much more rapidly than one who had not seen it would be apt to suppose. When the fore part of the body is to be advanced, the oblique intercostal muscles pull the ends of the shields upwards; and when the length of the under part is to be contracted in order to bring up the rear of the animal, the muscles, which extend parallel to the axis of the spine, draw the ribs together. The celerity with which this creeping motion is performed is much more considerable than those who are in the habit of associating locomotion on the

earth with feet only would be ready to believe; and it affords a proof of a very general and very delightful principle in the working of nature, namely, that it is of very little consequence what form of organ is provided for any particular purpose; for, be the organ what it may, the labour is always sure to be done in the best manner, and with the minimum of exertion on the part of the animal.

The whole of the *Ophidia* can swim, although some take the water more readily than others; and there are several that live habitually in it. There is, however, no ophidian reptile that is furnished with gills, and entitled, as so furnished, to be called an aquatic animal. Their mode of swimming is by flexures of the body, which are chiefly performed in the vertical plane, or in the cross direction to those of the eel; and, as they have no fins of any kind, this is an advantage to them, as it enables them to ascend and descend by the flexures of the body alone, which they could not do if the flexures were lateral, unless they were possessed of lateral fins to serve them as means of support.

Considered in its mechanical structure, the alimentary apparatus of all the *Ophidia* is very simple; and the process of digestion depends upon the solvent power of the gastric juice, and very little on the action of the vessels. The gullet and stomach, in the serpents of large gape especially, have far more capacity of distension than those of any other animals, the wide-mouthed fishes not excepted. The stomach is little else than an enlargement of the gullet; and both have a solvent power. This is necessary, if, as it is said, the great crawling serpents swallow a deer, all to the horns, which continue sticking out from the sides of the gape, until the solution of the body has proceeded so far that they drop off.

The organs of circulation and breathing are also simple. The heart has two auricles and one ventricle, and only a portion of that which returns from the systematic circulation, is sent to the lungs. These lungs consist of a single sac, having large cells on its walls, and being situated in the cavity of the abdomen. The windpipe and the larynx are membranous; and thus the animals have no voice but hissing, which is produced by the passage of the expired air through the opening of the larynx, without any action of the membranes of that organ. The hiss accompanies excitement, and corroborates what we have said of the increase of respiration being necessary to work up the system of the animal to its full heat. In their production some are oviparous, and some ovoviviparous; those which have the former habit are more prolific, and consist of most of the harmless serpents; and those which have the last are less prolific, and belong chiefly to the true serpents.

Ophidia are all creatures of wild nature, for which there does not appear to be much place or use after man begins to cultivate extensively. They accordingly disappear before the progress of improvement, the dangerous ones first, and the others afterwards. Many of the savage tribes eat their flesh, which is said to be wholesome and nutritious; and there was a time when feeding upon the flesh of vipers was considered as one of the best means of preserving and increasing female beauty. It is said that, when man began to eat turtle in those parts of the world, women ceased to eat vipers; but whether this did or did not arise from their despairing of carrying on the war successfully with the luxuries of

the table, the story does not inform us, and the point is of too grave and deep a nature for our philosophy.

The classification of reptiles need not occupy us long. The four orders of *Chelonia*, *Sauria*, *Ophidia*, and *Batrachia*, into which it is usually divided, are tolerably well defined in their general characters, though the *Ophidia* certainly break the gradation, which is tolerably regular in the other three.

Of *Chelonia* there are two sub-orders, *Testudina* and *Chelonia*. The first of these is very numerous both in species and in individuals, and they are much more widely distributed over the surface of the globe. They inhabit the land and the fresh water, both in rivers and lakes; but there are none of them in the sea. They are the animals which are properly called tortoises.

There are usually reckoned four distinct genera of *Testudina*. 1. *Testudo*. With the shield hemispherical, solid, and covered with plates nearly of the consistence of horn, but not fibrous. The feet club-shaped, with five toes on the fore-feet, and four on the hind ones; the latter blunt, and all the toes fitted for digging. They are all inhabitants of the land; they inhabit chiefly the warmer parts of the world. There are about twenty known species, which are formed into several sub-sections, on account of differences in the form of the shield and breastplate. 2. *Emys*. With five sharp claws on all the feet, and the toes webbed, so as to fit them for swimming. The shell hard, the head retractile, and the last plates of the shield capable of shutting down upon the posterior margin of the breastplate. There are at least forty different species of them, inhabiting the water or its margins, and burrowing in the mud in the season of dormancy. They are called mud-tortoises, and some of them box-tortoises, from the power they have of closing the shells against each other anteriorly, posteriorly, or both. 3. *Chelys*. The shield cased with horny plates, the toes webbed and five or four in number, and the neck contractile. There are about fifteen species, some of them inhabiting the southern parts of the eastern continent, especially Africa and New Holland, and the others the tropical parts of America. 4. *Trionyx*. The feet pectinated, and in general only with three toes armed with sharp claws. The shell with a membranous covering, ending in a flexible edge. Found in the fresh waters, chiefly those of tropical or warm latitudes. The known species are about ten in number. Some of the animals of this sub-order have shells useful for various purposes in the arts, and the animals themselves are occasionally kept as curiosities; but they are of comparatively little value. Some of them are animals of very fierce and predatory dispositions.

The *Chelonia* properly so called are more interesting and more useful animals, though the species are fewer in number. They are all inhabitants of the sea, and the flesh of some and the shells of others are of considerable value. For a notice of them, and some hints respecting the former sub-order, see the article *CHELONIA* in this work.

The order *Sauria* are still more numerous, and some of them are animals of considerable interest, though more on account of their strength and ferocity than of their value to man, which is very limited. There are five families of them—crocodiles, lizards, iguanas, geckos, caméléons, and skinks. The crocodiles are chiefly inhabitants of the water, especially

of the larger rivers, and they are found only in the warm latitudes. They are the most formidable of all the saurian reptiles, though their power is in the water, rather than upon the land. All the rest are slurred over, in ordinary language, under the common name of lizards, which, however, ought to be restricted to a few only out of the number. They are land animals, and some of them are tree animals, climbing and jumping about with much ability. The flesh of some of the species is much esteemed as food; and some of the smaller ones are of a little use in clearing habitations from insects. Altogether they are an inoffensive race; but many of them are hideous in their forms, and furnished with crests and elatable or inflatable membranes, which add to their rude and coarse appearance.

The *OPHIDIA*, which literally means serpent-shaped reptiles, have been noticed apart from the others in a previous part of this article. There are, strictly speaking, only two families of them; but one of the families admits of considerable subdivision, besides the genera of which the several sections of it are composed. Snakes and true serpents are the grand divisions or families. The genera of which their family is composed are not very numerous, and they are all harmless in their dispositions, though some of them are guilty of plundering the nests of birds, and doing other depredations in wild nature. The true serpents consist of many more genera than the snakes, and there are many more varieties among them. Some have the power of going at nearly the same speed with either end foremost; some simply swallow their prey, and others crush it to death in their folds, while there are a very few that are said to live chiefly upon succulent matter, and they are the only animals in the order that do so. Others again are armed with poison-fangs, though they form the minority of the section of true serpents in species, and are not proportionally so numerous in individuals as those which have no poisoning apparatus. Of the poisonous ones, some have no teeth in the upper jaw-bones properly so called, except the poison-fangs; but they have these fangs more completely developed than the others; they have also all the parts and workings of the poisoning apparatus more complete; and, in as far as the infusing of venom into the punctured wounds made by the fangs is concerned, they are the most destructive and deadly of all the serpent race. Their fangs are so formed that the covering of very few animals is proof against their puncture; but fortunately for the rest of the living world, they are animals of very retired habits, and seldom make an attack unless they are alarmed. The rattlesnake and the viper may be considered as the two typical forms of them; but under the type of the viper there are many varieties, some of the small ones of which are highly dangerous, especially in the warm countries where vegetable and animal poisons of all kinds are the most deadly. The poisonous serpents which have other teeth in the upper maxillary bones, besides the poison-fangs, though not perhaps quite so deadly in their venom as those which have the fangs only, are perhaps more dangerous, because, from there being several teeth on the same part of the jaw with the fangs, which move along with that in the same manner as the fangs do, one is in danger of not supposing that they are poisonous. All the teeth which are on this part of the jaw are understood to partake of the nature of fangs, and to

be ready to perform the same office, in the event of any casualty happening to them. Generally the real fangs are the ones most in advance, though this is not always or necessarily the case. The fang is, however, always the largest one, or, if there are two fully developed ones in the same side of the jaw, the probability is that they are both capable of instilling poison into the punctures which they make. Of this subdivision of the waters—not of the fresh water only or chiefly, but rather of the sea—the land ones, some of which grow to the length of seven or eight feet, have been confounded with the crushing serpents, which are not poisonous; and indeed there are many points in the history of both which have not yet been cleared up in a very satisfactory manner. The naked serpents are perhaps the most singular of the whole order. They are, in some respects, more like worms than serpents, and they spend no small portion of their time deeply buried in the mud and slime of the marshes, but still they are vertebrated animals, and true serpents.

Of the *Batrachia*, the frogs, after which the order is named, are by far the most numerous, and the most widely distributed. But, as we have already given some notice of them in the article *Frog*, we need not add any more in this place. The other members of this order do not admit of being classed into any group more comprehensive than genera; and of some of these there is only a single species, and that species both local and rare in its locality.

We must now close this very brief and very important notice of the class of reptiles. If our limits had admitted, we could easily have made it longer; but there are so many parts of it upon which we have no correct information, and indeed no information at all, that a greater number of words would not have afforded a corresponding increase of information. Yet the reptiles are in themselves a very singular department of living nature; and, although none of them are inviting animals, and some are very repulsive, yet they occupy a place which renders the knowledge of them of great importance in obtaining a proper understanding of the other parts of the system, as they stand intermediate between the mammalia and birds on the one hand, and the fishes on the other; and also between the past and the present in the history of the globe and its inhabitants.

RESEDA (Linnæus.) A genus of annual, biennial, and perennial herbs and undershrubs, belonging to the natural order to which the genus gives a title, viz. —

RESEDACEÆ. A natural order, containing a single genus, but of which there are twenty-three species. They are mostly worthless weeds, found in Europe and North Africa. They differ from the order *Cruciferae* in the capsules being unilocular, and the stamens indefinite, as well as in the seeds being destitute of an umbilical cord. Except the *R. odorata* (mignonette), for its delightful fragrance, and the *R. luteola*, the dyer's wood or weed, cultivated for yielding a yellow dye, none of the other species are worth notice except to botanists. They are increased from seeds.

RESTIACEÆ. A natural order, containing nine genera and twenty-nine species of "rigid inelegant, often leafless plants, with the habit of *Cyperaceæ*, or true *Juncea*." They are weeds of the southern hemisphere, and uncultivated.

RHAGIONIDÆ (Leach; **LEPTIDES**, Macquart.) A family of dipterous insects, belonging to the divi-

sion *Brachocera* of Macquart, having the wings slightly extended during repose, and not resting upon each other, with several complete cells. The antennæ are short, with the third joint mallet-shaped, with a terminal seta; the palpi are filiform, or conical and external, the proboscis generally exposed; the anterior trochanters elongated, and the tarsi with three pulvilli.

This family is but of moderate extent, the species being of a moderate size. They are often met with upon the trunks of trees and on flowers, and occasionally are to be observed sucking the juices of other small insects which they have captured. The genera are *Rhagio*, *Leptis*, *Chrysopilus*, *Spania*, *Clino-cera*, and *Atherix*. The typical genus, *Rhagio*, is distinguished by having the palpi generally lying upon the proboscis, the third joint short and conical, and the style of the antennæ terminal. There are several British species, the type being the *Rhagio scolopaceus*, a common species, half an inch long, with the thorax black, the abdomen buff colour, with a row of black spots. This insect is well known to fishermen under the name of the down-hill fly, the insect being always observed, immediately upon settling upon the trunk of trees, to fix itself head downwards. The habits of one of the insects of this family, the larva of which feeds upon ants, is detailed under the article *LEPTIS*.

RHAGIUM (Fabricius). A genus of coleopterous insects, belonging to the family *Lepturidæ*, having the antennæ not more than half the length of the body, and the terminal joint of the palpi large and triangular; head large, nearly square; and the thorax with a lateral spine. They are handsome insects, of moderate size, which frequent flowers, especially those of the white-thorn. Types, *Leptura inquisitor*, *bifaciatum*, &c.

RHAMNACEÆ. A natural order, chiefly shrubs and trees, containing eighteen genera and above one hundred and seventy-one species. They have simple alternate, rarely opposite, leaves, and small, free deciduous stipules, which are sometimes wanting. The inflorescence is either axillary or terminal, and seldom solitary; the calyx free, or adherent to the germen, without sepals; the petals stand on the throat of the calyx; the stamens are definite, opposite the petals, if present, and alternate with the clefts of the calyx; the germen is free, or more or less adherent to the calyx, and immersed in the fleshy disc, and two or four-celled; the styles are equal to the carpels, and the stigmas are simple.

In this order we find the buckthorn, Christ's-thorn, zizyphus, the jujube, &c. Many of the species are medicinal, or useful as dyes; and the *Zizyphus lotus* yields a fine African fruit. The fruit of the *Z. vulgaris* and *Z. jujuba* are favourite desserts in Italy and Spain, either fresh or dried, as a sweetmeat; and a pleasant pectoral lozenge is made of them by the French pharmacians.

The leaves of *Ceanothus Americanus* form the New Jersey tea, and are used in some parts of America instead of the Chinese leaf.

All the genera are easily propagated, and thrive in loamy moor-earth.

RHAPONTICA (Decandolle). A genus of hardy perennial herbs, mostly natives of Switzerland. They belong to *Compositæ*, and were formerly called *Centaurea* by Linnæus. They are increased by division, and do well in the common soil.

Rhinoceros.

RHEUM (Linnaeus). A highly-valued genus of fleshy-rooted herbs, all of which are medicinal, and almost all of which are cultivated. The genus belongs to *Polygonaceæ*.

The cultivated rhubarb is in every garden, and much more an object of the kitchen-gardener than ever it was by the medical herbalist. It is now one of our most favourite and useful vegetables, answering the purpose of all kinds of baking or boiling fruit, and at the most acceptable seasons, viz., throughout the winter and spring months.

Many new varieties have been raised from seed prized for the immense size of their leaf-stalks, the part used in cookery. No plant is easier of cultivation, and no one forced with less trouble. A new sort, called the Goliath, is now very generally cultivated. The roots prepared for medical purposes are chiefly imported from Turkey.

RHEXIA (Linnaeus). A genus of handsome herbaceous plants, natives of America, and belonging to the fine order *Melastomaceæ*. Whether potted or in the open ground, they only succeed in peat-earth.

RHINANTHUS. A genus of annual plants, natives of Europe, belonging to the natural order *Scrophularinæ*. Two of them are British, where they are called "yellow-rattle;" very common in every damp meadow.

RHINOCEROS (*Rhinoceros*). A genus of pachydermatous mammalia, and one of the most singular of the whole race—singular as many of the rest are. Though all the characters and most of the habits of this genus of animals are very peculiar, yet the "horn on the nose," on account of which the name is given, and is merely the expression in Greek, is certainly the most extraordinary part. It is a true horn, and indeed more completely a horn than any other appendage to which this name is given, as it contains no sort of bone, and has no immediate connection with the bones of the animal. When we say "horn," in the case of these animals, we are to be understood as speaking of the substance only; for most of the existing ones, as well as of those which are now met with only in a fossil state, and generally, if not exclusively, in places where none of the living animals are met with, have two horns, generally a large one and a smaller one, not placed laterally, but in the rear of it, so that the centres of the bases of both are on the mesial line and on the nose; whereas the horns of the other animals are on the forehead, connected with the bones of the cranium, and in part composed of prolongations of these.

The nasal bones of the rhinoceros are strongly formed and vaulted, and otherwise fortified for supporting the base of the horn, but there is no immediate connexion. The horn is altogether a production of the skin, as is the case with all the heavy substances formed on the mammalia, on what part soever of the body they may appear. No part of the body in the mammalia appears to be capable of secreting horny matter but the skin, and the skin does not appear to be capable of secreting any other kind of permanent matter. There are particular glandulous pores or follicles for the secretion of this matter, and, according as these are situated, so is the distribution of the matter produced; and according to their size and distribution it is fur or hair, or bristles, or horny appendages of some kind or other. Various circumstances affect its production in the same animal. If it is transported from a cold climate to a warm one,

the pores producing the hair or fur become abortive in part, and the coat gets thinner; and if the change of climate is made the other way, the opposite results are produced. The quills on the porcupines, and the spines on the hedgehogs and some other animals, appear to be of the nature of single hairs, each produced by one follicle, and not by the agglutination of several into one mass, for they are not liable to split longitudinally.

The bristles of the hog, on the other hand, do appear to be the production of several pores; for, though they are compactly soldered together at their basal parts, they are easily split at the points, and generally partially so split in a state of nature. Nails, claws, and all the true horns, including that of the rhinoceros among the rest, are always produced from numerous pores or follicles; and, though the substance of the epidermis appears to proceed toward them, as we can trace by the descent of a temporary hurt on the back of the thumb or finger, passing along the nail as a white spot; yet, if the follicles are destroyed, they are not again produced; or, if they are injured, the production of them is deformed. If a nail, horn, or a hoof, is entirely torn off, together with the roots, as we call them in ordinary language, it never again grows. In nails and claws, and also in hoofs, the growth appears to be constant; but in many horns it is annual, the different years appearing as separate rings on the basal part of the horn, which can sometimes be separated from each other without much difficulty.

The horn of the rhinoceros grows on a disc, which appears to be very closely set with pores, the fibres from which come into contact as soon as they issue from their pores, and thus they are closely soldered together, as is the case in all the horny appendages. We cannot say that these productions of horn are absolutely without life, but they have in themselves very little sensibility, unless they have a near and immediate connexion with the bones, and in that case the sensibility appears to reside chiefly in the periosteum. The horn of the rhinoceros, originating as it does in the skin only, has none of this sensibility. The form of the disc of skin to which it is attached, and the fact of its attachment equally to all the parts of that disc, give it a strength of base which no other horn possesses; and its fibrous structure throughout makes it secure against fracture by any cross strain. The circumstance of its being placed over the bones of the nose, too, completely prevents any concussion of the brain, even from the most violent use of it; and its central position admits of its being made use of with the whole power of the animal. It is thus one of the most formidable weapons of defence in the whole animal kingdom, and one which can be used with the least pain or injury of any kind. It may also be worn down to the very stump without inconvenience to its owner; and one in the gardens of the Zoological Society of London, at the Regent's Park, had the horn worn down to a mere stump by habitually using it against the timbers of its den. This formidable weapon is, however, a defence merely, that is only to be used against the enemies of the animal, or sometimes, perhaps, in tearing its way through branches, and other obstructions, in the tangled places which it frequents; for the rhinoceros is strictly a vegetable feeder, and not furnished with any apparatus for biting.

The characters of the teeth are not so constant as they are in many genera; but the cheek-teeth, which are the ones that determine the nature of the food, are much the same in all the species. None of them have any canine teeth, and the incisors vary in number and size, and are sometimes wanting, at least in the adult animal. The incisive teeth, when complete, are four in each jaw, two larger and two smaller, and sometimes the one of these, sometimes the other, are placed in the intermediate part. The cheek-teeth, in each side of each jaw, are seven in number, with transverse ridges on their crowns, and those in the middle part of the jaw are usually the largest. The alimentary canal answers to the coarse vegetation upon which the animals feed. The stomach is simple, and of very ample dimensions; the cæcum is also very ample, and the intestinal canal is long. Great size in these parts is indeed one of the characters in which all the *Pachydermata* agree the most; and though there are differences among them, we necessarily conclude that they are fitted for subsisting on a coarser vegetation than the *Ruminantia*; while their progressive history assigns their general distribution over both cold and warm latitudes to an earlier period. The same difference may be stated, with a few exceptions, of the *Rodentia*, and also of the whole of the *Quadrumana*; and these are the only other orders of mammalia which are decidedly vegetable in their feeding.

In their general appearance they are strong and massive, but dull and unwieldy animals, though they are more compact and indicative of strength, in proportion to their size, than the elephants. Their aspect cannot be said to be absolutely ferocious, but the form, and especially the motion, of the upper lip, gives them a snarling appearance. This lip is produced considerably beyond the nostrils, and also beyond the lower lip; it is pointed, and so far prehensile as considerably to assist the animal in feeding. The motion of the point is accompanied by another motion of the middle part, which displays the teeth, deepens some furrows near the gape, and gives a forbidding aspect. It seems best adapted for feeding on substances at or above the height of the axis of its body; but, though the animal is not very rare in some localities, very little is known of the details of its action in wild nature, as it cannot be approached either with ease or safety.

The legs are short and thick, sometimes approaching the character of those of the elephant, and indicating that the animal must be much on its legs—as indeed all animals are which subsist upon very coarse food. The terminations of the feet are, however, very different from those of the elephant. Each has three toes, though very imperfectly developed externally of the membranes. The middle one is largest; the two lateral ones are nearly of equal size; and all the three are furnished with short flat and blunt hoofs. The head and neck are rather short; the ears of moderate size, and pointed, bearing a slight resemblance in shape to those of the bison. The eyes are very small and lateral, so that the animal cannot see well immediately in front. The tail is of moderate length, or rather small, round toward the root, and flattened in the sides toward the extremity. The skin is of immense thickness and strength, much gathered into folds in some of the species, and for the most part destitute of hair, at least in the species now living. When there are a few hairs on

the tail, they are usually found on the upper and under edges of the flattened part, and there are generally a few hairs on the margins of the ears. The female has two mammae seated in the groin; but the mode of gestation, and the other particulars of the production of the young, or the duration of life, are little known. It is pretty well established, however, that in the Indian species the time of gestation is nine months, and that the young, of which there are never more than one at a time, begin to have the appearance of the horn when nine months old; and it is supposed that the others follow the same law.

The bones of the animals are remarkably dense and compact, equal, as it is said, to those of the fore leg and paw in the lion; and Mr. Burchell, who had many opportunities of observing the animals in Southern Africa, mentions that a pewter bullet was flattened by striking against them. The cervical vertebrae have the number which is common to all the mammalia, namely, seven. The vertebrae of the back are nineteen in number, the ones at the shoulder with large spinous processes. The lumbar vertebrae are three, the sacral ones four, and those in the tail twenty-two. There are nine true ribs and four false ones on each side.

The skin of the rhinoceros is "cudgel-proof" at all times, and hardly penetrable by a leaden bullet, unless urged on by a strong charge of powder. When dried and prepared, it is exceedingly hard and tough, and can be penetrated with difficulty by any ordinary instrument. The flesh is much esteemed, at least by the natives of some of the countries which the animals inhabit.

Though there are considerable differences of size among the living species of the genus, they are all large animals, and powerful in proportion to their size; but some of the extinct ones appear to have been much smaller, and others of them still larger. As existing, they are all natives of the eastern continent, and of the most tropical parts of it; and none have hitherto been found in the fossil state in America. We must not be too hasty in inferring from this, however, that none of the genus ever existed in America, for the portions of the soil of that vast continent that have been explored amount to so trifling a portion of the whole, that they do not warrant us in saying positively what is not there. The analogy would, however, lead us to conclude that there never has been any, as there are none living in the tropical parts. On the eastern continent they appear to have been at one time distributed over every latitude, for they have been met with in various parts of Siberia; and, as is the case with the extinct elephant of the north, one at least has been thawed out of the polar ice, in that part of the world, in such a state of complete preservation, as to show that it had been adapted to the rigour of a cold climate, as it was pretty thickly covered with hair.

As now existing, the rhinoceros may be considered as the most aquatic of all the *Pachydermata*, excepting the hippopotamus, and the ones which, next to it, feed upon the rankest and coarsest vegetation. They do not, like the hippopotami, spend the greater part of their time in the water; but they resort frequently to it, not only to drink, but especially to wallow in the mire, which they do something in the same manner as hogs. They do not, however, at any time range the forests at a distance from the water, as is done by the elephants; and though they have a

little tendency to be gregarious, they do not assemble in such herds as these. We believe, that neither the lion and the tiger on the one hand, as predatory animals, nor the elephant on the other, are fond of invading the territory of the rhinoceros. The claws and teeth of the former, could make but little impression on the thick skin of the animal; and its vigilance is so great, that it is not easily taken by surprise. The sight is, as we have said, not very penetrating, and there would be no great scope for its exercise, either in the finding of food, or the discovering of danger, in the slimy jungles which the animal inhabits. But the hearing and scent are very acute; the first being chiefly the one which gives the alarm when danger approaches—though the scent also is said to be useful in this way; and the scent being the grand means of finding out the favourite food. What is usually called the sense of touch cannot be very acute in the general surface of an animal which has so very thick a skin as the rhinoceros; but the prehensile part of the upper lip appears to have that sense in a considerable degree. The animal is also by no means deficient in the sense of tasting; for those that have been kept in a state of confinement have shown much fondness for sweet-tasted food, especially for sugar.

From the peculiar places in which the living rhinoceri are found, and their partiality for water, we are enabled to draw some conclusions with regard to what must have been the general condition of the earth at the time when they were more generally distributed over it. This, it must be borne in mind, has no reference to difference of temperature, taken upon the average, and referable to the influence of the sun upon the earth as the grand cause of the difference of seasons. It has no reference whatever to any variation in the orbit of the earth, in the inclination of the axis of rotation to the plane of that orbit taken on the transverse or principal diameter, or to anything else of an astronomical nature, whatever that may be supposed to have been. It is not the great astronomical principles of the solar system that regulate the nature of the earth's productions, whether vegetable or animal; it is the condition of the earth itself, and chiefly its condition with regard to humidity, which, extending over a large surface, tends more to equalise the temperature of the different seasons, than to fix their average degree. That a tropical climate was not required in the high latitudes, in order that the animals might resemble those now found only in tropical climates, is shown by the fact, that both the elephant and the rhinoceros of the north were really animals adapted for a cold climate.

The inference from this, respecting the state, of the higher latitudes of the eastern continent, when they were inhabited by those animals up to the very shores of the Northern Ocean, is easily drawn. They must have been, in great part, covered with marshes; and the vegetable remains of the same period that are found in some of the accumulations, show that a more vigorous marsh vegetation must have grown in such places, than there can possibly grow at the present day. If we attend to the remains which are found still deeper in the earth, and which, we may, therefore, suppose have been deposited there at a period still more early, we find the remains of plants which have evidently grown in moist places, and perhaps in the water, and which have rivalled

in their magnitudes the tallest pines that grow upon the comparatively dry surface of the same regions at the present day, but which do not extend into such high latitudes as these tall children of the marsh must have done. Along with these last, we find the remains of creatures which must have been of giant bulk when in the living state; some of which, from the structure of their skeletons, must have lived in the waters only, and others alternately in the water and air probably, without any indications in other skeletons that they ever could have walked or even crawled on the surface of the earth. All these have been vertebrated animals, or animals with an internal spine or back-bone, supporting the cranium and jaws at the anterior extremity, and drawn out into a long tail at the opposite one. The cranium in them all is of very small size as compared with the whole skeleton, which indicates that they must have been animals of very limited resources, and of little general energy. The jaws, on the other hand, are produced to a length which, compared even with those of the crocodiles of our day, appear absolutely monstrous and deformed. These jaws are furnished with teeth having no resemblance to the teeth of the mammalia, and no distinction of kinds in the different parts of the mouth. They are simply prehensile teeth, and not adapted either for killing and tearing, or for any kind of mastication or bruising of the food. The teeth to which they have the greatest resemblance, are those of the larger saurian reptiles, which are either absolutely inhabitants of the water, or found immediately on its banks.

It is of course impossible for us to refer these strange animals to any one class of the system of vertebrated animals as at present existing on the earth, not only on account of the dissimilarity of their organisation to that of anything which we now see alive; but from the total dissimilarity of the whole vegetable and animal kingdoms, and of course of the appearance and state of the whole face of terrestrial nature. But the class which they resemble the most, in so far as can be determined from the remains, is that of the reptiles. Vast powers of endurance, for long and almost indefinite periods of time, and violent momentary action, when aroused to it by the proper stimulus, are the leading characters of the great reptiles of the present age of the world. But these are known to us only as inhabiting warm climates; and therefore we can establish no proper analogy with them, without falling into the same error into which the earlier speculators upon such subjects were led, in considering the northern elephant. They had made up their minds as to the degree of average temperature necessary for an elephant; and having settled this part of the matter, they came to the natural but not very philosophical conclusion, that in the earlier stages of its history, the tropical parts of the world must have had a tropical climate. In good time, however, there appeared sufficient evidence for the refutation of this; for first the northern rhinoceros, and then the northern elephant, were found in a state of sufficient preservation for shewing that both were animals fitted for enduring the very rigours of a polar climate. And, in order to make the demonstration that they did actually live in such a climate complete, they were found preserved in ice in which they must have been frozen up in a very recent state, and kept from the decomposing influence

of the atmosphere for one knows not how many thousands of years; so that there cannot be a doubt that the principle which is established by actual observation in their case, was equally true in the case of every other remain, whether of more or of less ancient date, which has been found or shall be found in the same latitudes; and the fact must be held as perfectly established, that the average climate of every zone in the world, as depending on the influence of the sun, was the same in the very remotest times as it is now.

To suppose otherwise, though perhaps not an unnatural supposition in the days of ignorance, was calculated to originate and confirm a very pernicious and inveterate error on the subject of Nature's grand system, the universe—or, taking it within the limits to which we can apply weight and measure, the solar system. The vulgar opinion is that we are the important part of this system; and that all the rest has been made and is conducted specially for us;—that there is not an event which takes place in the economy of our globe, or a character displayed, or an action done by the highest or the humblest individual of the human race, without “the stars in their courses” having a hand in it. They who once swallow this, need, of course be under no apprehensions of choking by the very largest mass of nonsense that imagination can picture; and they would do only due honours to their *gull*-ability, if they were to label themselves; “Nonsense swallowed here in the largest possible quantities;” in the active performance of which, they might play the vulture, and undo part of the mischief which they and their forefathers in folly have done. Now when we come to consider that the sun contains considerably more than three hundred thousand times as much matter as our earth, and that Jupiter, which is so remote from us as to have but very little influence even in the matter of gravitation, more than three hundred times, it seems very absurd to suppose that any of these bodies should have the least influence in the topical changes which go on upon the surface, or in the interior of our little globe; and that they should take cognisance of our doings as low down as

Cutting corns and letting blood,

really appears to be the acmé of absurdity. It is worse than this, for it takes away our attention from the real causes, and then cuts us off from all possibility of obtaining that knowledge which would really be useful to us. That the action of the sun upon the earth as the dispenser of light and heat is, in itself, a constant quantity, dependent solely upon the unalterable laws of the solar system, and capable of being estimated for every latitude with perfect mathematical accuracy; and that it is the same, and has been and will remain the same, in all years and ages, is a principle which we must take along with us if we wish to turn what we observe of seasons and plans to the proper account. In addition to this, the sun exerts its gravitating influence; and the moon does the same, and also cheers us by the variableness of its borrowed light. But, in addition to this, these bodies do nothing. All the rest is the effect of terrestrial causes; and it is in these causes that we are to seek our explanations as to why any one region is fitted for one kind of plants and animals at one period of history, and for another kind at another period. There is something humbler than this in philosophy, but of more immediate practical use; it is this kind of

study which leads us to the proper means of so working the soil to the solar influence, as to be able to obtain the most abundant and permanent return from the land; to adopt, in short, such a mode of culture as shall enable us to feed ourselves without impoverishing our fields. It may not be either possible or desirable to cultivate the northern lands back to the state in which they were when they were tenanted by the rhinoceros; but the covering of the surface with green leaves during the time of the sun's greatest ardour, has produced many wonderful effects in different places of our own island; and the invariable result has been, that in proportion as cultivation has reduced the heat of the summer, the intensity and duration of the winter have been diminished; so that an approximation has been made to permanent cultivation—keeping the earth in a state of producing something useful all the year over. This is an incalculable advantage; for the long winter used to exhaust the whole of the year's stock in the days of our fathers; and the summer, notwithstanding all its heat, was a season of sorrow; during which, famine came in to destroy a people who had no food, in the most heart-rending manner. Then the rains of the autumn came with terrible violence, scourging the fields and floating away much of the produce; and the transition from burning heat to cold damp was so violent, that the season of plenty was also a season of death.

These are only a very few of the simpler points of that knowledge to which the proper study of the rhinoceros leads, as an easy and necessary matter; and we may apply, in the same manner, the history of any other animal, which now appears only as a fragment in a few peculiar localities, but which the remains found in the earth prove to have been at one time more generally distributed. We shall now notice the species of rhinoceros, in as few words as possible.

INDIAN RHINOCEROS, (*R. Indicus*). The old name of this the first rhinoceros known to naturalists, was *Unicornus*, or one-horned; but the discovery of another with only one horn, and yet with specific differences sufficiently marked, rendered this name no longer descriptive as a specific one. This powerful animal is not distributed over the breadth of continental India, but confined to the marshy jungles in the lower valleys of the great rivers, especially the Ganges, and its affluent the Burhampootra. The country there has a peculiar character among even Indian countries. The rains come with both monsoons, the north-east as well as the south-west, and they come in very great quantity; so that, for the greater part of the year every where, and the whole of it in many places, the country is a swamp; a swamp which remains under the shade of that most luxuriant vegetation which it produces, despite the great heat of the sun. This is the grand residence of the rhinoceros; and it points out what must have been the character of vegetation in those places from which the rhinoceros has vanished, when that animal was alive in them.

The characters of this one are:—a single horn on the nose; the skin is marked with deep furrows or plaits behind the shoulders and the thighs; and there are also deep folds under the throat. The skin is indeed folded and furrowed in many places, as if it were too large for the owner. The hairs on the skin are hard and smooth; but they are so few, as scarcely to make any appearance, excepting a few on the tail and the margins of the ears. The head

is short and triangular ; but the nasal bones are well developed, and form a strong vault, on the summit of which the base of the horn rests. The eyes are very small ; and there are two strong incisive teeth in each jaw. When in health, the skin of the animal is blackish grey, with a slight tinge of violet. When full grown, it attains the length of eight or nine feet ; but it does not stand much more than half the height of the elephant. It is a strong and powerful animal and easily excited, in which state it is equally bold and persevering in its attacks. What the natural enemies of the rhinoceros may be, it is not easy to say ; though its proneness to make the attack, which has no reference whatever to the finding of its food, would lead us to suppose that this pugnacious instinct has not been given to it in vain.

In consequence of its boldness and strength, the hunting of the rhinoceros is one of the most splendid and hazardous of the wild sports of the East. It is to be sought for in the jungles, and is often found in parties of about half a dozen, led on by the biggest of the whole, as is the case with the herds of elephants. In the tall vegetation of the Indian jungle, the sportsmen cannot hunt for this animal unless they are mounted on elephants ; and they find it necessary to go in bands, so that while some of the elephants are receiving the charge of the rhinoceros, the others may take aim and wound them. A single one is said, in the first instance, to seek safety in a retreat into a closer part of the jungle ; but, if again roused, it advances to the attack. Its object appears to be to get at the elephant on the side ; and passing the horn in below it, to wound it in the belly, or fairly rip it open. The elephant is also said not to attempt using the tusks, which would not, of course, be able to toss so weighty an animal. What may be done in a state of nature we have no means of knowing, for nobody has recorded, and probably nobody ever saw, a battle between a rhinoceros and an elephant in wild nature, nor probably between a rhinoceros and any other creature. But in cases of hunting, the elephant does not appear to have any means of warding off the attack ; but wheels round, and receives it on the hinder part of the body, on which the horn has not much effect in the way of laceration ; but the impetus of the animal is such, that it hurls the elephant to the earth ; and this it will continue to do again and again for some time. It is not unlikely that the elephant, if free in wild nature, would continue to receive these attacks till its opponent were exhausted, and then have recourse to its own mode of warfare with advantage ; but this is merely matter of conjecture, upon which there appears to be no means of getting real information.

As far as can be judged from the few specimens which have been kept in menageries in Europe, the rhinoceros does not appear to be in any way ferocious ; though its efforts to break down its prison-house and obtain its freedom are often repeated. In such places the elephant and the rhinoceros are shown to very great disadvantage, on account of the smallness of the dens or cages in which they are pent up. This is considered necessary to the safety of the spectators, and it also suits well with the economy of those who pay the expenses of the spectacle. Truly, however, an animal pent up in a crib which barely enables it to turn round, is but a miserable sight,—a little better than a stuffed skin we grant, but only a little better. If we are to see the animal in such a

way as to have any idea of what it is in a state of nature, we must give it free scope for the performance of its natural action ; and thus all that we can know of a living rhinoceros, kept as these animals are usually kept, amounts to little more than an artificial knowledge of them.

Pretty circumstantial details are given, by M. F. Cuvier, of one which was kept in the royal menagerie at Paris. It was but a young animal, yet of considerable size, measuring about eight feet in length, and standing five feet and a half in height. From the shortness of the legs, and the compact massive form of the body, this must have been an animal of great weight and power ; and if it had been allowed space enough in which to acquire its momentum, its den would have required to be of great strength. Its general deportment was mild and gentle ; it knew its keeper, was not wholly unobservant of persons and things around it, had no reluctance to be fed, and obeyed a few very simple commands—upon receiving food after each act of obedience. No particular attention appears, however, to have been paid to the calling out of its instincts in any way that could be considered as even preparatory to domestication ; and its efforts to get out of the prison-house were so violent and incessant, that many liberties were not taken with it. The skin was, as has been stated of the genus, nearly naked of hair. It was marked with tubercles, and of the same dark purplish grey that we have mentioned, only in the depths of the folds it was flesh-coloured. This skin had to be wetted with water every day, otherwise it was apt to chap and crack. The irregularities of the skin on the head, and the external surface of the legs, were formed into elongated ridges, and gave these parts the appearance of being furrowed. These furrowed parts are naturally the ones which have to undergo the severest fatigue when the animal is finding its food or making its way among the close vegetation of the jungle.

RHINOCEROS OF JAVA (*R. Sondiacus*). This is another species with only one horn, and was first discovered, or at all events described, by the French naturalists Diard and Duvancel, when they, in part at least, explored that island of natural wonders. It is smaller, at least in the specimens that have been seen, than the Indian species. The length, from the membrane of the tail to the ears, is six feet ; and from the ears to the extremity of the upper lip, about two feet more ; but as the animal carries the head something in the manner that the hog does, with the axis nearly horizontal, the whole eight feet may be said to be included in the continuous length. The tail is

only about a foot in length; and the legs, though very stout, are short, the total height, when standing, not being more than four feet. The horn is situated about the middle part of the line occupied by the two horns in the species named with these, which is, perhaps, a very little higher upon the nose than that of the Indian species. The horn always appears to be much used by the animal in some operation or other; for it is ground or rubbed down, and is sometimes reduced to little more than an inch in length, and much rounded, so that it cannot be very powerful as a weapon. In the young animal there are four incisive teeth in the upper jaw, two upon each intermaxillary bone, and the whole standing close to each other. These appear, however, to be merely milk teeth; for they are shed early, and replaced by only two, which however are of much greater size. These milk incisors are cylindrical in their form and blunt on the crowns; but the teeth which come after them are broad and flat, but too blunt in the edges for being considered as chisel-shaped, or for cutting any substance clean off, though they cut with considerable force against the long incisors of the lower jaw, or rather form a grand point of support for those to rub against. Though all the teeth in this, as well as in the other species of rhinoceros, are blunt, yet they must be powerful gnawing teeth, as the size and weight of the nasal bones and the horn afford a powerful resistance; and thus the whole force of the lower jaw can be exerted on the substance which the animal breaks in pieces. The skin of this species is very much plaited behind the shoulders, under the neck, and on the outsides of the legs. The folds on the shoulders surround the whole body, those on the legs extend the whole length of these members, and the folds on the neck hang like collars on the under part. Besides these folds, the skin is roughened by prominent tubercles, for the most part in the shape of regular pentagons, well defined. These do not, however, in the least approach to the nature of scales; they consist merely of accumulations of the epidermis; and the only hairs that are found upon the body of the animal arise from slight depressions in the centres of their pentangular tubercles. The hairs are of a black colour, and short and stiff; and they are very few in number, excepting on the borders of the ears and the edges of the flattened part of the tail. The accumulation of tubercles on the skin of this animal, is a singular character among the class to which it belongs, though there are traces of marking on the skins of some of the other *Pachydermata*—even on those of the common hog, as may be seen in those parts of saddles which are made of the prepared skin of that animal. Though this species has latterly been met with only in Java, it is highly probable that it may exist in the other islands of the Sunda group; but it does not appear to exist in any part of the continent of Asia. It must, however, be borne in mind, that the part of the continent nearest to these islands, namely, the Malay peninsula, has been but little explored, as the treacherous character of the inhabitants renders the exploring of it a matter of no small risk.

The two species which have been noticed are the only one-horned rhinoceri which are now to be found in the living state; and the greater part, if not the whole, of those which are found fossil in the colder latitudes, appear to have had two horns; so that the one-horned species appear to have been, in all ages of the world, confined to the localities in which they are

now found. The two-horned ones, in further proof of their having been once more generally distributed, and in their nature better adapted to climates of different temperatures, or at all events more obedient to those natural causes which adapt them to these, are found both in the eastern isles and in Africa. There is one difference between these animals which is worthy of notice, as showing the particular quality of the two-horned ones, upon which their adaptation to climate seems in a great measure to depend. The skin is more free from plaits and tubercles, and more plentifully covered with hair, than on those which inhabit the most equatorial climates. There is, therefore, in the skin of these species a much greater disposition to form hairy matter, and not mere accumulations of cuticle, than there is in the other. The heat of tropical climates, even where they are most under the influence of the sun, and have less need of protection from cold than in higher latitudes, has a tendency to form hairs on the body. We believe we may also add that, although they love moist places, and are fond of bathing themselves and wallowing in the mud, yet the application of water to their skins is not so absolutely necessary as it is to the skins of the single-horned ones, which produce epidermis rather than hair or any other substance of a horny consistency. They are thus driven to the water by the action of the hot sun upon their bodies; and the action of the cold also tends to champ and harden their epidermis much more than it does that of the others. In the two-horned ones, again, there is a power in the skin, upon which the cold seems to act, though to what degree, in the species now living, we have no correct means of ascertaining; we know, however, that in all cases where such a power exists, it is always in so far under the influence of climate, and changeable with changes of that. The sheep bears little or no wool in India; and the dog is almost naked in tropical climates, well clothed in the middle latitudes, and coated with very thick fur in the polar ones—even if the variety is the same, for all dogs are of the same species. It may be said that these are animals which accompany man, or are carried by him, over all the regions of the world; and that they are especially fitted for this by the readiness with which climate modifies them into an agreement with its leading characters. So far we admit this; but the admission is one of degree only, and not of kind. There is no general property in the skin of any animal covered with hair or fur, which does not also belong to every other which produces the same substance, however different may be the quantity and quality; and if the property exists, it is always in so far under the controul of climate, though of course in a less degree when it is in itself weaker. We have instances of this in some of the other *Pachydermata*, which are generally distributed over climates of different characters. Of these, the most familiar is the common hog; and any one who visits the places may see that the hogs of the warm and dry parts of the south of England are almost naked, while those of the north of Scotland, especially in the cold and upland districts, are quite shaggy. Hogs' bristles are imported in large quantities from Russia, but no such article is to be found among the imports from India or Central Africa. These circumstances will suffice to show why the remains of the two-horned rhinoceros should be found in the cold latitudes, and not those of the one-horned; and also that there is no need of having recourse to

any supposed difference of temperature as depending on the action of the sun, between the present time and that at which the rhinoceros was a common inhabitant of Europe and the north of Asia ; for the change from being very humid to being very dry is quite sufficient to explain the circumstances. This principle would lead to many other conclusions respecting the removal of an animal from one climate to another, and the means of applying art so as to facilitate its adaptation to the change ; but we have not room, neither is this the proper place for entering upon the subject, interesting though it be. We shall therefore proceed to notice the living species of two-horned rhinoceri.

AFRICAN RHINOCEROS (*R. Africanus*). This is unquestionably the typical animal of the two-horned species ; and it is the largest and most powerful, and apparently the most numerous, of the whole. It ranges the whole of the African continent from the Cape of Good Hope to the upper part of the valley of the Nile ; and although the size and colour vary in some of the localities, or at least in some individuals, it is probably the same specific animal throughout the whole extent of its range.

It is probable that this species was known to the ancients, though the two-horned rhinoceros first discovered by modern naturalists appears to be the one which is now called the Sumatran rhinoceros. Pausanias mentions, under the name of the Ethiopian bull, an animal which agrees better with the characters of the African rhinoceros than with those of any other animal with which we are acquainted. What gives greater appearance of truth to this, is the fact that the profile of a two-horned rhinoceros is found on some medals struck by order of the emperor Domitian ; and there are hints in various ancient writers, respecting this animal, as distinct from the rhinoceros of India. Farther, we can draw no conclusion respecting the animals which the ancients may have met with in Northern Africa, than those which we now find in the places that the ancients visited. For many extensive tracts of that country which were humid in ancient times are now dry ; and many which were covered with rich pastures are now desert. Accordingly, many animals, both herbivorous and predatory, have disappeared ; and there can be no doubt that, in proportion as the country became dry, the rhinoceros would be among the very first to depart ; and that, as the desert continues to increase, the pasture of these animals will be narrowed in the same proportion.

This animal, at least in the adult state, has no incisive teeth, and even the intermaxillary bones appear to be wanting. Some, however, are mentioned of smaller size, and with two incisors in each jaw ; but it is probable that these, though the observers have considered them as distinct species, are only young animals which have not shed their milk teeth. This is rendered the more probable by the circumstance of those species which have two incisors in each jaw when adult, having four milk teeth in each of the same ; and it is also to be borne in mind that a milk tooth is an appendage of the gum rather than of the bone ; and that, therefore, the existence of such teeth is not incompatible with the absence of intermaxillary bones.

The skin of this species is smooth and without folds, though there are more lines traceable on those parts where the folds are upon the others ; and Bruce (we believe) mentions that some, at least of those in the interior of Abyssinia, have decided folds on the skin, and the anterior or longer horn much compressed laterally. The base of the anterior horn is placed farther towards the extremity of the nose than that of the single horn ; the flexible and prehensile part of the upper lip begins nearly at it ; and the arch of the nasal horns brings it nearly on the same plane with the eyes. This anterior horn is conical and sharp-pointed, about two feet in length, and curving slightly backwards for the whole of its length. The second horn is situated a little above this one, and over the eyes, with its base in a sort of depression of the frontal line. This one is nearly straight, and not above half the length of the first one ; but it stands on a base of equal dimensions, and is therefore the stronger instrument of the two, though not the more formidable in appearance.

It is considerably larger than the Indian rhinoceros, being found as long as twelve feet, or even more. One measured by Mr. Burchell was eleven feet two inches along the mesial line, and eight feet four inches in the circumference of the body. The tail was compressed laterally toward the distal extremity, and measured one foot eight inches. These are probably the proportions of the animal in all the varieties of its size ; but there are many of larger dimensions than those that have been named. Burchell states, upon the authority of the natives of southern Africa, that there is another species found in the interior different from that which is met with nearer the sea, being much larger in its dimensions, and feeding on grass ; whereas the one commonly observed nearer the coast feeds on the leaves and tender twigs of trees. This is not impossible ; but it is quite as philosophical to suppose that the enlarged size may be the result of richer pastures than the animal meets with near the sea ; and this is rendered the more likely from its being known that the size of the Indian rhinoceros depends a good deal upon the nature of its pasture. As to the one living upon coarser food than the other, that proves nothing as to difference of species ; for every grazing animal lives upon the finest and most succulent food that it can procure ; and we have evidence not only that the Indian rhinoceros prefers succulent vegetables to those which are hard and coarse, but that it prefers sugar to these. The vast size which this animal of the interior of southern Africa is said to attain, and especially the largeness of the head and the breadth of the prehensile lip, certainly are differences ; but the substantial characters are so much the same, that we

should hesitate much before admitting that there are more than one species of rhinoceros in Africa.

But whether there is only one species, or more than one, the rhinoceros seems to be much more at home in Africa than in India. In the latter country it is not found in the interior, even where the banks of the rivers are marshy; and nearer to the sea it is not found but in the jungles, or their close vicinity. The African appears to be much more a ranging animal, and though it resorts to the water several times in the course of the day, it moves over the dry places in the intervals, and feeds on the branches of the trees, especially some of the species of acacia. This ranging habit demands a little more resource, and when an animal requires that, it is always given. The lion of southern Africa, especially at some distance into the interior, where his pastures are abundantly supplied from the time that he is a cub, and all his powers are, in consequence, fully developed, is certainly a much more formidable animal against very large prey than the tiger of the Indian jungles. He is not so little, or so capable of making his way in a tangled cover as the tiger; but tangled cover is not the character of the country in which the lion is most in his place. The lion is not a sea-side animal, or an animal of the low and swampy places by the banks of the great rivers. The plains, where there are alternations of pasture and bush, are the places where he is most in his element; and though he sometimes lies in wait in the bush, he more frequently prowls along the plains, and steals within the reach at which he can capture his prey, under cover of the night rather than of the herbage.

It is probable that under such circumstances, the lion, which makes a prize of the Cape buffalo and the giraffe, may, in the absence of other prey, and when excited by the joint influence of the heat of the season and hunger, attack the rhinoceros itself; and, should he once fairly seat himself on its back, he might be able to ride and gnaw it till it fell, and then of course it would be his prey the same as though it were a weaker animal. That this may be the case is rendered more probable by the hide of the African rhinoceros, though still a tough and compact one, not being nearly so much so as that of the rhinoceros of India. This, of course, enables the animal to be more fleet in its motions; and along with this fleetness there appears to be an increased acuteness of the senses. Perhaps it may be as well to hear Mr. Burchell for a little upon this point, as he had excellent opportunities of studying the manners of the African rhinoceros, and improved those opportunities well. "Their smell (sense of smelling) is so keen," says Mr. B., "and nice that they can know, even at a great distance, whether any man be coming towards them: on the first suspicion of this they take to flight. Therefore it is only by approaching them against the wind, or from the leeward, that the hunter can ever expect to get within musket-shot. Yet, in doing this, he must move silently and cautiously, so as not to make the least noise in the bushes as he passes through them; otherwise their hearing (the hearing of the rhinoceri, not the bushes) is so exceedingly quick, that they would instantly take alarm, and move far away to some more undisturbed spot. But the dangerous part of the business is, that when they are thus disturbed, they sometimes become furious, and take it into their head to pursue their enemy; and then, if they once get sight of the

hunter, it is difficult for him to escape, unless he possess a degree of coolness and presence of mind, which in such a case is not always to be found. Yet, if he will quietly wait till the enraged animal make a run at him, and will then spring suddenly to one side to let it pass, he may gain time enough to reload his gun before the rhinoceros get sight of him again, which fortunately it does slowly and with difficulty. The knowledge of this imperfection of sight, which is occasioned perhaps by the excessive smallness of the aperture of the eye (its greatest length being only one inch) in proportion to the bulk of the animal, encourages the hunter to advance without taking much pains to conceal himself; and by attending to the usual precautions just mentioned, he may safely approach within musket-shot."

The arts of the hunter would not, however, avail him much, were it not for the musket; and we want a good account of the manner in which the aborigines deal with this powerful animal, when they have not the use of fire-arms. The poisoned arrow and the hassaguay bring down the strength of the lion; but the arrow would need to be aimed by no ordinary archer, and discharged from a bow of no ordinary strength, which could penetrate the mail even of the African rhinoceros. It may be, however, that, as the skin, thick as it is, is very sensitive, the poisoning of it by a puncture of no very great depth may be sufficient to overcome even this animal. It is a curious fact that, let the people of a country be as low in the scale of civilisation and as destitute of anything which we call knowledge as they possibly can, they are never without the means of conquering the most powerful animal that is to be found in their country. Thus man, taken merely as man, and without any reference to the degree of his knowledge and civilisation, always establishes his title to that dominion over the other creatures which was at first given to him by his Creator. Not only this; but it very often happens that those rude men, with their apparently simple weapons, are much more efficient against the powerful animals, than civilised men are with those of a superior construction. In India, as in southern Africa, the hunt of the tiger or the lion is seldom undertaken without the natives being of the party; and in all parts of America, when the hunt is attended with great difficulty and danger, the Indian is always, by way of eminence, the hunter. This seems at first sight a curious fact, but it is a fact; and the reason of it is not of very difficult explanation. The mind of the savage is concentrated upon a few operations; and for this reason he does them better than they can be done by a civilised man, whose attention is divided among a great multiplicity of subjects. Besides this, the civilised man goes to the hunting of those animals with very little knowledge of them compared with that of the savage, who has been trained from his infancy in the manner in which he is to deal with them; and it would be absurd to suppose that civilisation should enable a man to do that which he does not know; and especially to do it better than one who knows it well.

SUMATRAN RHINOCEROS (*R. Sumatrensis*). This is a smaller species than the two-horned rhinoceros of Africa, even if we admit that there is in that quarter of the world a larger and a smaller species. It appears, like the African one, to be more an animal of the interior of the country than the Indian species, or that of Java; for, although the accounts mention

that the natives of the coast and those of the interior call it by different names, yet the animal seems to be the same. The coast name is the general one for the rhinoceros in the language of several Eastern nations, especially the Malays; and the name in the interior is probably that used by the African negroes, of whom there are still remnants in most of the larger islands to the south-east of Asia, even where the Malays are in possession of all the coasts. If a traveller were to come from a far country where no such animal as a cow were known, and see a cow, and hear its name in England, in the Lowlands of Scotland, and the Scotch Highlands, he would be very apt to conclude that there were three species of the animal, as well as three names; and we may expect to find much the same mistake made by travellers who visit such countries as Sumatra.

The Sumatran rhinoceros, in the specimens that have been seen by Europeans, is only between five and six feet in length, and between three and four in its greatest height. It is of course a much less formidable animal than most of the other species. Its skin is without the decided folds which mark the single-horned ones, and also the wrinkles which more or less pucker the skin of the African species. The skin altogether is softer and thinner than that of the others, and it is much more abundantly supplied with hair. We might suppose this from the thinness of the skin; and the two circumstances taken in conjunction would lead us to conclude that this species should be obedient to climate; yet it does not appear to occur except in Sumatra, which is one of the most tropical islands on the surface of our globe, being intersected by the equator in very nearly the middle of its latitudes.

The colour of this animal is dark brown, by which it can be at once distinguished from the other rhinoceri of the East, although it had not two nasal horns, the one of which is sometimes not very conspicuous, especially in the young and the females. Although there are some hairs on the body, there are none on the flat sides of the tail; but the upper and under edges have them tolerably thick. In the young state there are four incisors in each jaw, but two of them are lost as the animal approaches the maturity of its growth. In this part of the mouth, therefore, it resembles the other eastern species, and differs from the African, though in the smoothness of the skin and the two horns it more resembles the African. The first horn is moderately large, although by no means so formidable an instrument as that of the African; but the second one is always very small, and often little more than rudimental. In the females the first horn is also only a small one. Of the manners of this species little or nothing is known; but as the cheek teeth are the same in structure as in all the others, it is natural to conclude that the mode of feeding and the food are exactly the same.

FOSSIL RHINOCERUS. The preceding notices contain all the existing species of those curious animals that have hitherto been made out, at least with so much certainty as to entitle them to notice in a short popular list; so that it remains only to take a very slight glance at those which have once inhabited the earth, but the whole of which are now entombed under its surface. As we have already alluded in a general way to these, and to the probable state of the temperate and cold latitudes, when these were inhabited by them, our present observations will be very few.

Rhinoceros with partitioned nostrils (*R. tichorhinus*). This is the largest of all the fossil species, and appears to have been the most plentiful, and the one which inhabited farthest to the north. Its remains have been found in many parts of Europe, and particularly in France, though perhaps that is owing to the greater attention which has been paid to the fossil remains of animals in that country. They have also been met with in Siberia; and this is a species of which a preserved specimen, nearly entire, was found in the ice, in the extreme north of that country, in the year 1771. The flesh, the skin, and the hair, were all in such preservation as to afford a perfect knowledge of what the animal had been when in the living state, and the hair was in such abundance and of such a nature as to show that the animal was able to bear the cold of the severest winter.

This extinct species has a considerable resemblance to the living one now found in Africa; but still, independently of its adaptation to a different climate, which of itself would perhaps not be distinction enough, there are other and more essential characters which show it to have been a distinct species. The bones of the head are much more elongated than in the African one; and, from the size of the discs on the bones which supported their bases, the horns, especially the second one, appear to have been larger. They appear also to have been more actively or powerfully employed, for the nasal bone is supported by a vertical septum or partition, which is not found in any of the living species. Like the African species, this is without intermaxillary bones, and of course could have had no incisive teeth in the upper jaw when of mature age. From the character of its bones, this must have been a large and powerful animal, equally capable of performing severe labour and defending itself against enemies, as for enduring the rigours of the northern winter.

Rhinoceros with simple nostrils (*R. leptorhinus*). This has been altogether a more slender and less powerful animal, and it has not inhabited so far to the north. The south of Europe appears to have been its principal habitat, as the bones have been chiefly found in Italy. From the discs on the bones of the head, it must have had two horns; but there is no partition to strengthen the nasal bone, and the bones altogether are much more slender in proportion to their length than those of the preceding species. From its southern habitat there is not the slightest chance that any more perfect remains of it will be found than simply the bones. As is the case with the former species, this one is without intermaxillary bones, and consequently must have had no incisor teeth.

Fragments of another species have been found in some of the collections of fossil bones in Germany, which appears to have been of considerable size, and to have been possessed of intermaxillary bones. Having them, it has certainly been different from any of the two preceding ones; but very few particulars are known respecting it.

Small Rhinoceros (*R. minutus*). The remains of this species have been found in France, and from them it does not appear to have been larger than a common hog. It appears to have been a very ancient species, for the bones have been found at the depth of eighty feet below the present surface of the ground, mingled with those of crocodiles and tortoises. Its incisor teeth appear to have very much resembled those of the rhinoceros of Java.

RHIPICERA (Latreille). An interesting genus of coleopterous insects from Brazil and New Holland, belonging to the family *Cedronitidae*, distinguished by the beautiful antennæ of the males, which are composed of from twenty to forty joints; each being furnished with a long and pilose branch, together forming an elegant flabellated appearance. The antennæ of the females are only slightly serrated, and are composed of fewer joints than in the other sex. The body is of an elongate-ovate form; the thorax short and convex, and the legs of moderate size. There are six or eight species.

RHIPIDURA—Fan-tail. A genus of birds, belonging to Cuvier's dentirostral family of *Pastores*, and nearly allied to the fly-catchers in their general habits. They are natives of Australia, a country which is as peculiar in many of its birds, as in its other productions. Their general characters are as follows: the bill short, depressed, wide at the base, and compressed toward the tip; the upper mandible keeled and crooked in the culmen, and notched toward the tip. The nostrils basal, oval, and nearly covered with hairs and feathers. The gape provided with numerous bristles, which are rather longer than the mandibles. The wings are of mean length, something resembling those of the fly-catchers, but more rounded, and therefore it is concluded that the birds are not capable of the same rate and extent of forward flight. The tail is long, rounded at its termination, capable of being spread out like a fan, and therefore well adapted for assisting the birds in rapid ascent and descent. The feet are of mean length, slender, and with the tarsi smooth. There are several species, but very little is known of their habits.

R. flabelliforme. This is the fan-tailed fly-catcher of Latham, and a bird which is by no means rare in the country inland from Sydney, between that place and the ascent of the Blue Mountains. It frequents the woods and bushes, in which it hunts for insects, darting upwards and downwards, rather than performing long flights. Its general colour is blackish fawn; with a spot behind the eye, the throat, the tips of the coverts, and the ends of the shafts of the tail-feathers, white; and the belly rust-coloured.

R. malacitoides is black, with the quills yellowish brown, and a spot behind the eye; the middle of the breast and abdomen white.

R. rubrifrons is blackish fawn, with the back, the forehead, a streak over the eye, the base of the tail, and the lower part of the belly, red; the neck black; the throat and breast white, spotted with black; and the quills fawn, with white tips.

RHIPIPTERA (Latreille; RHIPOPTERA, Lamarck). Names proposed by these authors for the order of insects previously described by Mr. Kirby under the name of *STREPSIPTERA*, which see.

RHIPIPHORUS (Bosc). A curious genus of coleopterous insects, belonging to the family *Mordellinæ*, which see for its characters, and an account of its parasitical habits.

RHIPODENDRON (Willdenow). A genus of African succulent plants, neatly related to the genus *Aloe*, and from which it has been separated. It belongs to *Hemerocallidæ*. They are managed in every respect like other succulents, that is, planted in light lime-rubbish soil, and allowed but little water.

RHIPSALIS (Gartner). A genus of succulent undershrubs, natives of South America and India. The flowers are icosaandrous, and belong to *Cistæ* of

Opuntiaceæ. The species are all cultivated like other succulents.

RHIZOBOLÆ. A natural order containing only one genus, namely, *Caryocar*, of which there are three species. The genus is remarkable for bearing the butter or suwatrow nuts. These have a rich oily flavour, and are used as a desert. The fruit of *C. glabrum* is eatable, and the nuts of *C. amygdaliferum* taste like almonds. *C. butyrosum* is the butter nut, and which are sometimes met with in our fruiters' shops. The species are large trees, natives of Guiana, and cultivated in our stoves.

RHIZOPHOREÆ. A natural order containing only two genera, and of each a single species as yet discovered. The genera are *Rhizophora* and *Carallia*. The *R. mangle* is the mangrove of Madagascar. They are arborescent, and are remarkable for growing upon the shores of the sea and rivers. The seeds have the singular property of germinating while enclosed within the capsule and adhering to the parent, and pushing forth a long subform radicle, which lengthens till it reaches the soil, where it takes root, and forms a new individual.

RHODIOLA (Linnæus). A genus of two species of alpine plants, natives of Britain and Siberia. The flowers are diœcious, and the genus belongs to *Crasulacæ*. In gardens the species are planted in light soil, and usually placed on lapidiums or rock-work.

RHODODENDRON (Linnæus). A genus of shrubs and trees which, from the beauty of their evergreen foliage, and highly splendid character of their flowers, attract the admiration of every beholder. The magnificence of the European and American species is only exceeded by the grandeur of the arborescent species from Nepal. Of these last we have now two or three species, and several splendid varieties procured by intermixture of the pollen of the trees of Nepal and shrubs of America and Europe.

The *Rhododendrons* are placed by Linnæus in his tenth class *Decandria*, and they belong to the proteus-like natural order *Ericææ*. They are all propagated by seeds or layers, and all thrive in leaf mould, moor-earth, and sand.

RHODORA (Linnæus). A genus containing only as yet one species, viz., *R. Canadensis*. It is a pretty early flowering shrub, and mostly before the leaves appear. It belongs to the *Ericææ*, and is treated like what are called American plants, namely, in heath-mould borders, though they are often potted for decorating the greenhouse in early spring.

RHOPALA (Dr. Brown). A genus of South American trees, bearing tetrandrous flowers, and belonging to the natural order *Proteacææ*.

RHUBARB. See *RHEUM*.

RHUS (Tournefort). An extensive genus of deciduous trees and evergreen shrubs, found in every quarter of the globe. The flowers are pentandrous, and the genus belongs to *Terebinthacææ*. They are chiefly hardy plants, and the greenhouse species are easy of management.

RHYNCHÆA. A genus of *Echassiers* or stilt-birds, belonging to the longirostral or long-billed family, and nearly allied to the snipes. They have indeed been classed with these and also with the rails by some authors, though they appear to have characters of their own sufficient for entitling them to be regarded as a distinct genus.

They are all natives of warm climates of China,

of India, of Southern Africa, and the isles to the east of that continent, and there is one at least a native of South America. They have the general air and gait of the snipes; but they differ much from them in their plumage, the colours of which are much more brilliant. In this respect, one remarkable character of them is the oscillated spots which mark the quills and the tail-feathers; the bill is also different in its structure. The generic characters may be stated as follow: the bill longer than the head, enlarged at the tip, much compressed, hooked at the tip; the mandibles of equal length and very slightly covered; the upper mandible furrowed for the whole of its length, and the lower only toward its extremity; the nasal grooves continued for half the length of the bill, and the nostrils linear and open; the feet of mean length, the tarsus longer than the middle front toe; the toes four in number; three to the front, totally divided from each other for the whole of their length, and one to the rear articulated higher upon the tarsus than the front ones; the wings of ample dimensions; the first, second, and third quills nearly of the same length with each other, and larger than any of the rest.

R. Capensis, the Cape snipe of some authors, is a bird about ten inches in length. The upper parts are of a bluish-grey colour waved with black; there are five bands on the head, one reddish, two grey, and two white; there is a broad band of black on the upper part of the breast; the belly is white; the coverts of the wings are ash, the lateral ones marked with four eye-spots of yellow, and the bill and feet brown. This species is subject to considerable differences of colour at different ages; and it has accordingly been figured and described as two if not as three species; the mature bird being *Capensis* of authors, the young *Variiegata*, and the intermediate stage being recognised as another variety if not species.

R. Sinensis. This, as the name imports, is a native of China. It is a smaller bird than the African one, being only nine inches in length; and it is also richer in the colouring; the upper parts are brown, spotted and streaked with red, bluish, and black; the head is streaked with black and white; the neck is mottled with grey, and whitish; the under parts are white, with a large gorget of black upon the breast; the bill and feet are black. The present species is a very pretty bird.

R. Indica is of the same dimensions as the Cape one, namely, ten inches in length. The upper parts are greyish-brown, without any wavings, lines, or spots of another colour; the head is white, slightly clouded with greyish-ash on the crown, and having two streaks of grey on the sides; the neck and breast are white, spotted with grey; the greater coverts of the wings are crossed by bands of black; the throat and belly are white, and the bill and feet black.

R. Madagascarensis is nine inches in length, and although some have considered it the same as the first-mentioned species, or, at all events, called it by the same specific name *Capensis*, it appears to be distinct. The upper parts are varied with black and grey, with some red on the coverts of the wings; there is a double streak, one part black and the other white, over the eye, and another of the same colours on the neck; the coverts and quills are brown rayed with black, and having upon them four eye-spots of red, with black margins; the under parts are white, and the bill and feet black; various writers upon

birds, and Temminck among the rest, who is usually correct to the very minutiae of species, are of opinion that all of those which we have noticed are one and the same bird in different states of its plumage; and certainly the differences which we observe among them are not greater than those which occur in the same species among birds with which we are better acquainted. Altogether, indeed, they are birds of whose nature and habits we know very little. From the countries which they inhabit, we might be led to conclude that, at some seasons at least, they can feed upon pastures much more dry than those that are usually resorted to by the snipes; but information is wanted before any certain conclusion can be arrived at respecting them.

RHYNCHÆNUS (Fabricius). An extensive genus of coleopterous insects, belonging to the section *Tetramera* and family *Curculionidæ*, having the antennæ strongly elbowed, and ten, eleven, or twelve-jointed, the three last forming a club; the rostrum long and deflexed, with the antennæ inserted near the middle; the body of an oval or rounded form, and the legs long, the tibiæ generally having a curved terminal hook. The genus has been greatly subdivided by Schopenherr and other recent authors.

RHYNCHITES (Herbst). A beautiful genus of coleopterous insects, belonging to the section *Tetramera*, family *Curculionidæ*, and sub-family *Atte-labides*, in the article upon which we have given the characters and figured the genus; and in the article *CURCULIONIDÆ*, we have given an account of the destructive habits of the *Rhynchites Bacchus*.

RHYNCOPHORA (Latreille). A sub-section of coleopterous insects, distinguished by having the head anteriorly produced into a snout or muzzle, with the mouth placed at its extremity. This sub-section corresponds with the Linnæan genus *Bruchus*, *Atte-labus*, and *Curculia*; of the arrangement of which we have already given a sketch in the article *CURCULIONIDÆ*.

RHYNCHOSIA (Loureira). A genus of North American and tropical plants, mostly climbers, and belonging to *Leguminosæ*. This genus was called *Glycine* by De Candolle and other botanists; but Loureira's name has been generally adopted. The greenhouse species thrive in sand and moor-earth, and are propagated by cuttings.

RHYPHUS (Latreille). A genus of dipterous insects belonging to the family *Tipulidæ*, having the antennæ short, sixteen-jointed; the proboscis advanced, cylindric, and rather shorter than the head; the ocelli three in number, and of equal size; the legs of unequal size, the posterior being the largest. There are two or three species which frequent the windows of our apartments, distinguished by their spotted wings. The larvæ, according to Reaumur, frequent cow-dung.

RIBES (Linnæus). A genus of shrubs found in many places of the northern hemisphere, of which the various species of the currant and gooseberry are familiarly known. The flowers are pentandrous, and the genus gives a title to a natural order, viz. *Grossulariæ*. There are several varieties of the common useful currant, and those of the gooseberry are innumerable. Both the currant and gooseberry are wholesome and useful fruits, and are applied to many economical purposes. The old varieties are perpetuated by cuttings, and new varieties are obtained from seed. The best currants are the Dutch white

and red. The black is highly esteemed by the confectioner; and one of the best gooseberries is the Warrington red.

RICE is the *Oryza sativa* of Linnæus, a tropical aquatic cereal, extensively cultivated, and of the greatest importance to the inhabitants of those warm countries where it succeeds.

RICHARDIA (Kunth). A genus of plants nearly related to *Dracontium*, and formerly called *Calla æthiopica*. It belongs to the natural order *Aroideæ*, and is a common plant in every greenhouse.

RICINUS (Linnæus). A genus of shrubs and annual herbs, natives of the tropics. The flowers are monœcious, and the genus belongs to *Euphorbiaceæ*. The *R. communis* is commonly called palmo-christi, from the hand-like form of the leaves. It is from the seeds of this plant the castor oil is expressed, and for which the plant is cultivated in the West Indies. In this country, the palmo-christi is treated as a tender annual, and planted as an ornament in the flower-border.

RICINUS (De Geer; NIRMUS, Hermann). A genus of bird-lice. See the article NIRMIDÆ.

RIEDLEIA (Ventenat). A genus of tropical undershrubs, formerly called *Melochia*. The species have monadelphous flowers, and belong to *Byttneriaceæ*. They grow freely in our stoves, and are easily propagated by cuttings.

RIPOGONUM (Forster). A genus of Australian climbers, bearing white flowers, and belonging to the natural order *Smilacææ*. They are greenhouse plants, and are propagated by division or by cuttings.

ROBINIA (Linnæus). A fine genus of trees and shrubs, almost all natives of America. The flowers are papilionaceous, and the genus is associated with the *Leguminosæ*. The *R. pseudacacia* is an elegant ornamental tree, producing very durable timber, and is the celebrated locust-tree of the United States, of which so much was written by the late Mr. Cobbett. The *R. hispida*, *R. rosea*, and *R. viscosa*, are all fine flowering plants. Most of the species ripen seeds from which they are raised, or the more choice sorts may be grafted on the common *R. pseudacacia*.

ROCAMBOLE is the *Allium ophioscorodon* of G. Don, a culinary species of onion, now but rarely cultivated. A peculiarity of its manner of growth is that of its seeds vegetating before they drop from the capsule. *Rocambole* is in no respect superior to the common onion.

ROCKET. This is the vulgar name of a genus belonging to *Cruciferae*, called, by Tournefort, *Eruca sativa*. A majority of the species are cultivated in various parts of the continent as greens, and the double varieties are admitted into flower-gardens. The *Hesperis matronalis* of Linnæus, a favourite border flower, is also called Dame's Rocket.

ROCK ROSE is the *Cistus purpureus* of Tournefort. The genus *Cistus* contains many species, all natives of Europe, and favourite plants in our shrubberies.

ROELLA (Linnæus). A genus of under-shrubs and annuals, natives of the Cape of Good Hope. The flowers are pentandrous and are arranged among the *Campanulacææ*. The species are pretty, and easily managed in the greenhouse.

ROLLER (*Coraciæ*—*Galgulus*). A genus of conirostral birds, in Cuvier's great order *Passeres*, omnivorous in their feeding, as most of the conirostral

family are, and arranged by Cuvier as intermediate between the more coloured and woodland members of the ocean tribe, and the birds of paradise. They are generally speaking handsome in their forms, and gay in their plumage, generally with more or less of metallic lustre. But they have a suspicious and magpye-like look, which almost convinces us that they cannot be altogether honest. Yet, notwithstanding this, the purity and the brightness of their colours entitle them to rank among the most beautiful of birds. They have, however, little to recommend them but the beauty of their colours; for their voices are harsh and disagreeable, and their manners are gloomy rather than lively.

They are all natives of the eastern continent, where they inhabit the depths of the forests, so that little opportunity of studying their manners can be obtained. They probably can subsist upon farinaceous or pulpy vegetable matters; but these are understood to form but a small portion of their food, and that only occasionally. Their principal food consists of worms, mollusca, and other small animals; and the living subject, and dead bodies in a state of carrion, are nearly the same to them. It is also probable, that they eat the eggs of other birds; but the fact as to this has not been clearly brought home to them in a sufficient number of instances, for enabling us to say that it is a general habit.

The generic characters are: the bill of mean length, higher than broad, straight in the greater part of the length, covered at the tip of the upper mandible, and with the toms, or margins of both mandibles, sharp, hard, and adapted for cutting. The nostrils are basal and lateral, half covered by a membrane furnished with stiff bristles, like feathers. The tarsus shorter than the middle front toe; the toes four, three to the front and one to the rear, all completely free to their articulations,—so that the foot is either a walking foot, or a hopping one, aided by the wings, as the particular action which the bird has to perform may require. The wings are rather pointed, the first quill is shorter than the second, which is the largest in the wing. The tail is generally speaking long, capable of spreading, and composed of firm feathers. The whole plumage indeed is firm and compact, and not liable to be injured by the motions of the bird among the thick branches in the woods. There are a good many species in the genus; but they have been increased much beyond the proper number, by including tarragons, pyes, and other birds, some of which do not belong to the same family, in the natural arrangement.

EUROPEAN ROLLER (*C. garrula*). Though this bird is called European, and appears in the south and east parts in considerable numbers, it is doubtful whether it is permanent for the year in any part of Europe. They appear to be summer migrants from Africa; for they appear in considerable numbers in Malta in the spring on their passage northward, and again in autumn on their way southward. They of course breed in those parts of Europe which they frequent; and thus they are natives, although they do not continue all the year round. They occasionally, but very rarely, make their appearance in Britain, though only as single individuals, which appear to have strayed out of the line of their ordinary migration. But still they keep so much in the cover of the thick woods, that a stray bird may occasionally breed in Britain without being observed. On the continent

they range farther to the north, for numbers of them cross the Baltic. They are, however, much more rare in the west of the continent, being rarely found in France farther north than Strasburg, and rarely, if ever in Holland, even as stragglers.

The length of the common roller is about thirteen inches, and it is a firm and compact bird in proportion to its length. The upper parts are of a brownish-fawn colour; the top of the head and upper part of the neck blue with green reflections; the lesser coverts of the wings bright violet-blue; the quills waved with blue, dull green, and fawn colour; the middle tail-feathers greenish-grey, and aquamarine green on the under sides; those next them dull green, and the external ones, which are a little longer than the rest, are of this same colour; the under parts of the body are aquamarine blue; and the bill and feet are reddish-yellow. The eggs vary from four to seven, and they are of a shining white, which is the general colour of those of the genus.

ABYSSINIAN ROLLER (*C. Abyssinica*) is a larger species than the one which visits Europe, measuring sixteen or seventeen inches in length. The back is orange-brown; the forehead, a streak over the eyes, and the chin, are white; the top of the head, the neck, the middle and greater coverts of the wings, and all the under parts of the body, are sea-green; the lesser wing-coverts and the scapulars are bright azure; the quills are rich blue, with the lips and margins of the inner webs black; the middle tail-feathers are greenish-black, the next ones blue at the basal part, and sea-green at the terminal, and the external ones, which are considerably longer than the rest, are sea-green at their bases, then crossed by a band of blue and black in the remaining portion towards the tips; the bill is black with the exception of the base of the lower mandible, which is white; and the feet are reddish. The female is smaller, has the lateral feathers of the tail less produced, and all the colours duller. The young have the upper part mottled with green and reddish, and the front, throat, breast, and flanks reddish. This is a very handsome bird; but it is subject to some variations of colour, and very little is known of its habits.

BENGAL ROLLER (*C. Bengalensis*), is perhaps not very accurately named after Bengal, as some of the authorities state that it is also found in Southern Africa. The upper parts are violet-green, with the lower part of the back and the rump clouded with green and blue. The larger coverts of the wings are

sea-green, the middle ones are clouded with green and blue, and the lesser and also the upper tail-coverts, are light blue; the quills are variegated with deep blue, sea-green, and black; the middle tail-feathers are blackish-green; and the others are deep blue at their bases, and black toward the tips and in the outer margins; the cheeks and lower neck are violet streaked with white; the throat is reddish, the breast russet, and the under parts sea-green; the bill is black and the feet grey; the length about thirteen inches. The female is rather smaller than the male, and has the front and the under part of the body reddish-white. The young have the anterior part of the head and the ear-coverts white; and the top of the head and upper part of the neck reddish-violet; the breast and belly are of the same ground colour, but they are streaked longitudinally with white; the upper parts are olive-green clouded with red; the coverts of the wings violet-red; the bill brown; and the feet red. There are some doubts about the bird being a native of Southern Africa, though it is thus stated by some authorities. It is rare indeed that the same species of animal, be it what it may, occurs in both these countries; and there have been so many instances of productions of India and the oriental isles being purchased at the Cape as African, that we require very strong evidence, in fact that of the very party who met with them alive in the wild state, before we can be secure against this kind of imposition. It is true that India and Africa are more abundant in birds of the genus than any other parts of the world; but, except in this instance, if it really be an exception, all the species of the one locality are different from those of the other.

BLUE-BILLED ROLLER (*C. cyanogaster*). This is an African species measuring about fourteen inches in length. The upper parts are olive-brown; the head, neck, and breast reddish, clouded with green; the rump and wing-coverts are blue; the quills green at the base, then blue and afterwards black at the tips; the tail-feathers are green; the neck and breast greenish-red; the under parts blue; and the bill black, and feet grey.

GREEN ROLLER (*C. viridis*). This is an Indian species about a foot in length. It is sea-green in the general plumage; but has the forehead and throat reddish-white, and the rump and tail-coverts bluish-green; the bill is black and the feet reddish.

TEMMINCK'S ROLLER (*C. Temminckii*) is an Indian species, about the same dimensions as the last-mentioned, but different in the colours. The upper parts are green; the top of the head, the nape, and the crest, are aquamarine blue; the neck, rump, coverts, throat, and all the under parts are bright shining blue; the bill is black, and the feet are reddish-brown.

There are several other species of roller, some natives of India, some of Africa, and some of Australia; but, excepting in size and colour, they do not differ from those which have been already noticed. Indeed, though the rollers are unquestionably very beautiful birds, there are very few genera which have got a shorter, or even so short, a story to tell. Excepting in their mere external appearance, and the countries which they inhabit, any one of them may be an index to the whole race.

ROSACEÆ. A natural order, embracing the greater part of the Linnæan class *Icosandria*, and a very conspicuous order of Jussieu's sub-class *Caly-*

cistora. This order contains forty-six genera, and not less than seven hundred and eighty-three species. Whether the genera be trees, shrubs, or herbs, there is a similitude in the character of their flowers which is obviously striking; and the single rose being a type so well known, facilitates the identification of the various genera. Among the trees there are the *Amygdalus*, *Prunus*, *Persica*, *Cerasus*, and *Eriobotrya*, which are also fruit bearers; among the shrubs, besides the type, there are the *Cratægus*, *Phorinia*, *Cotoneaster*, and *Cydonia*; and among herbs we have the useful strawberry, the *Potentilla*, *Geum*, and *Tormentilla*.
